ORIGINAL ARTICLES.

UNUNITED FRACTURES.[1]

BY OSCAR H. ALLIS, M.D.,

SURGEON TO THE PRESBYTERIAN HOSPITAL, PHILADELPHIA.

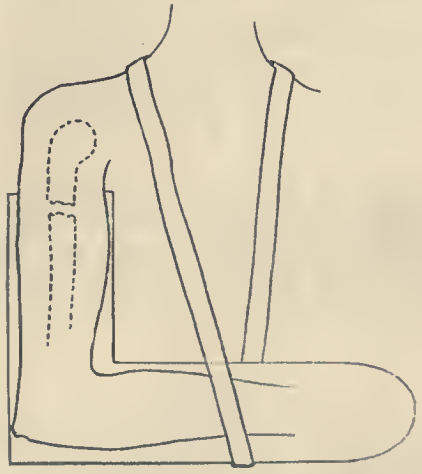
FOR knowledge concerning the frequency of non-union in fractures we turn naturally to hospital statistics, and are astonished to find no recorded cases. This would imply that hospital surgeons were loath to put on record their failures, or that hospital treatment was superior to that in private practice; but neither conclusion is correct. Hospital records recognize but three classes, viz., "cured," "relieved," and "died." Now, few cases of simple fracture require more than two months, and were a case to be dismissed at the end of three or even four months, it would neither be true as a matter of fact, nor just to the surgeon treating the case, to place it on record as a case of "non-union." I have made no attempt to collect cases, but can recall eighteen cases—eight of the humerus, five of the femur, two of both bones of the leg, two of both bones of the forearm, and one of the jaw. These cases were treated in the Pennsylvania, Presbyterian, St. Mary's, Jefferson, and Hahnemann Hospitals, and in private practice. I have no means of estimating the frequency of non-union, but feel that the estimate of Hamilton (1 : 500) is much too low.

The most extensive statistical tables with which I am acquainted (Agnew's) give much interesting material, from which I formulate the following: That fractures in long bones occur most frequently near the foot and wrist, while non-union occurs most frequently near the shoulder and pelvis. In other words, the further from the trunk, the more frequent the fracture; the nearer the trunk, the more frequent non-union. If syphilis, scurvy, old age, wasting disease, paralysis, fevers, etc., were the cause of non-union, then it would occur most frequently in the parts in which fracture was most frequent, but this is not the case. Fracture in the long bones occurs more commonly in the leg above the ankle, but non-union is more than twice as common in the humerus near the shoulder.

Surgeons at the present day believe that non-union is chiefly the result of faulty fixation, as a result of which the reparative process is disturbed. This disturbance is from uncontrolled or uncontrollable muscular action: the latter when the patient is suffering from delirium; the former when the patient is conscious, but, either through neglect or over-anxiety to help himself, resorts to harmful muscular activity.

To secure the most perfect fixation, the profession resorts to splints, and sometimes the object of fixation is defeated by the very means adopted to secure it. This is illustrated in the case of the long rectangular splint used by many practitioners in *all* fractures of the humerus. A glance at Fig. 1 will show that the upper fragment receives no support from the splint, while, when the hand is removed

FIG. 1.



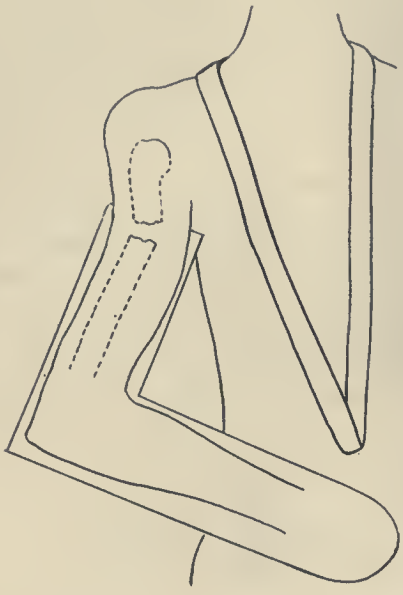
from the sling (as it invariably is as soon as the soreness leaves the part), the long splint will itself compel the fragments to separate as in Fig. 2. In such a case my practice has been to place thorax, shoulder, arm, and forearm in a plaster-of-Paris splint.

When suffering from fracture in the upper third of the humerus shall the patient be permitted to rise and go about? If we ask those in whom non-union resulted, they will tell us that attempts to rise in bed always caused the fragments to move. Whether or not I have seen an unusually large number of ununited fractures I cannot say, but the operation for their relief is so formidable, and the entire loss of time so great, that I now insist on recumbency in many cases that I would formerly have permitted to

[1] Read before the College of Physicians, Philadelphia, December 2, 1891.

rise. It was a remark of my late gifted colleague, Dr. Richard J. Levis, that there was as good reason why a man should go to bed for a fractured clavicle as for a fractured femur. Certainly the bed is the place for the most perfect rest, and under no circumstances is rest more desirable than when Nature is repairing a fracture.

FIG. 2.



I have stated that insecurity of fragments is the chief cause of non-union. Authors speak of the interposition of muscular tissue as a possible cause. If this is slight, the repair is not affected; but if

FIG. 3.

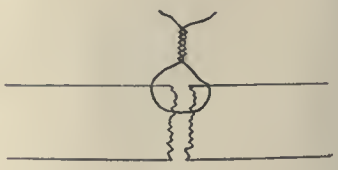
the two fragments are widely separated, when fragments transfix muscular fiber; or when in the leg or forearm a considerable fragment is lost from one bone only—under these circumstances non-union may take place. I was taught a useful lesson in one of my cases[1]: After cutting down upon the fractured parts, I found the fragments widely separated, and the fractured surfaces facing in opposite directions (Fig. 3). They had made a half-revolution upon each other, and were as distinct as if they had been in separate individuals. An interesting feature was the peculiarity of the healing over of the ends of the fragments. They each resembled the stump after amputation. In amputations Nature seems conscious of having no splinting to do, and hence we see no circumferential bone-proliferation, no temporary core, but instead a healing over with compact tissue. In my case Nature seemed to recognize that any attempt at union would have been useless, and therefore made no effort.

Surgical methods to secure bony repair. These are: (1) to stimulate reparative action without penetrating the seat of fracture; (2) to stimulate reparative action by means of irritants carried to the seat of the injury; (3) to boldly expose the fragments and reunite them by means of artificial agents.

I shall confine my remarks to the last head.

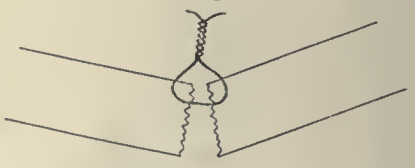
Operations that expose the fractured surfaces vary in degree. The simplest method of uniting the bones is by means of wire. A small awl or small chisel is usually carried to the seat of injury, and the ends of the bone thoroughly scarified; a wire is then introduced as represented in Fig. 4. In cases

FIG. 4.



so treated the fragments sometimes unite firmly, but it is not that the wire plays any part in fixation. (Fig. 5.) It is rather that the wire by its presence

FIG 5.



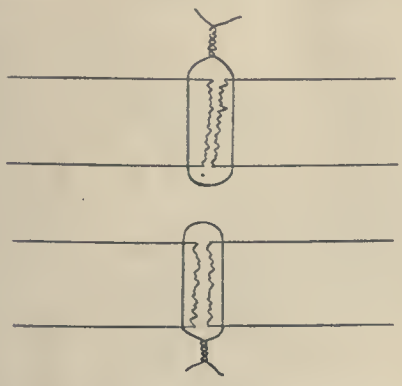
keeps up the inflammatory process so necessary to adequate bone-production. Such cases get well on the principle of the seton, not by the law of fixation by wiring.

The wires are best used in non-union of bones of the forearm and leg. In the arm and thigh, in which we have but single bones, the wire is of little value as a means of fixation. When wires are used to fix

[1] Case treated in the coal regions and sent to Jefferson Medical College Hospital with non-union.

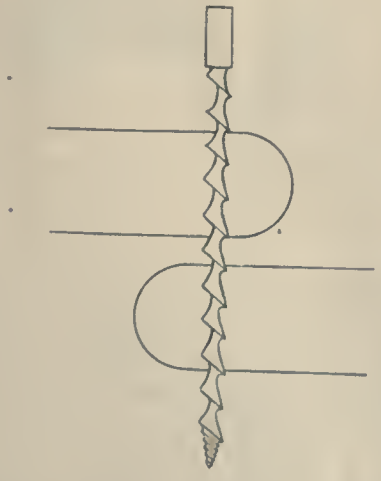
the bones of the forearm, the best results are obtained when the wires pass entirely through each fragment. (Fig. 6.) Under these circumstances the bones are so securely fixed that union is almost certain to follow. In such operations it is well to approach the radius and ulna by separate incisions, and thus avoid communication between them. By this means bridges between the radius and ulna may be avoided, and function restored with pronation and supination. The wires may be retained for two months. I use copper wire—a single strand, soft, pliable, but strong enough to hold the fragments.

FIG. 6.



I have never employed pegging by means of ivory or bone pegs. Theoretically it is a captivating thought to peg fragments with a material that will be absorbed—to close the wound and secure union by first intention. Practically the pegs act as foreign elements, and are not absorbed; suppuration takes place; fixation is not satisfactory; and if success follows, it is not due to the pegs.

FIG. 7.



Nothing can compare in efficacy with the screw as a means of fixation. In some form it has long been familiar to the profession. The elder Pancoast invented one that, from its size and character, was intended (1) to pierce the fragments without preliminary incision; (2) to bind them together; (3) by its presence to excite adequate inflammatory action. As the application of the screw was subcutaneous, it was uncertain in its action; and, as there was a thread the whole length, the fragment could not be approximated after the screw had taken hold of both fragments. (See Fig. 7.) I am familiar with its use in two cases. The first occurred when I was surgical interne at the Philadelphia Hospital. Dr. Maury employed it in non-union of the femur in the upper part of the middle third. The resulting inflammation was considerable, and before the screw was withdrawn repeated hemorrhages of a serious character took place. Bony union was finally established with about three inches of shortening, and the patient, a man in the prime of life, was restored to active manual labor. In the second case the elder Gross employed the screw in the case of a man, aged about forty-five, with non-union in the middle third of the humerus. Union took place with almost complete paralysis of the forearm, probably due to injury of the musculo-spiral nerve.

Volkmann has called attention to the bridge-splice, a means of splicing long familiar to mechanics. The principle is sufficiently well illustrated in the accompanying cuts, and needs no description.

FIG. 8.

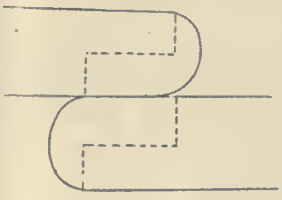


FIG. 9.

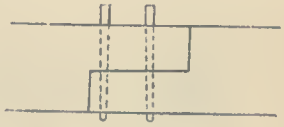

I have performed the operation twice, and in each instance secured bony union; but I shall not employ it again, because the result as represented in Fig. 9 is unattainable. The carpenter, with rule, gauge, squares, miter-boxes, and vice, may take two independent pieces of wood and so mortise them as to secure close joints and linear perfection, but the surgeon who makes three independent cuts in each fragment, held at best only in the grasp of an assistant and shaking with each forward and backward motion of the saw, finds that he has no possible guide but his eye, and must not be surprised if his best effort more nearly resembles Fig. 10 than the one given by Volkmann (Fig. 9). In my second employment of the bridge-splice, I encountered a difficulty that gave me much uneasiness, though the result was satisfactory. In this case non-union in the lower third of the femur had resulted, and, after

making my splice and inserting my screw, I was annoyed to have one fragment slip from its fellow, as shown in Fig. 11. This I could not prevent, but the final result was satisfactory.

FIG. 10.

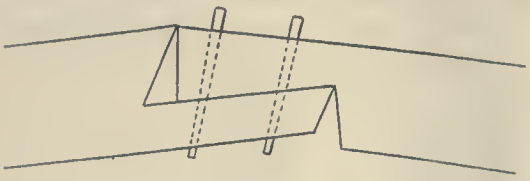

FIG. 11.

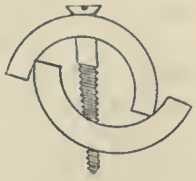
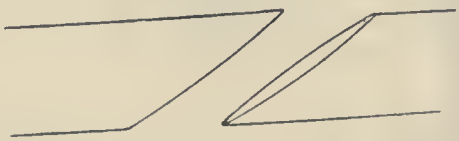


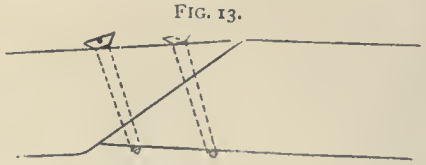
Since this mishap I have confined my efforts to the simple bevelled splice (Fig. 12) in single bones, *i. e.*, in humerus and femur. It gives the best surface-approximation; it exposes the least amount of bone

FIG 12.



surface; it is more easily executed; and with it, when either one or two screws are used, the approximation is more satisfactory than can possibly be obtained with bridge-splice and pegs.

FIG. 13.



I have been using carpenter's screws for about four years. I was induced to adopt them from the fact that screws long enough to project from the wound, like those of Pancoast and Gaillard, were unnecessarily irritating. I select slim steel screws sold at hardware shops, and am guided as to their length by the size of the bone and the obliquity of the screw-holes. *The hole for the screw in the proximal fragment should be so large that the thread will not get a hold upon it. The screwhole, however, in the distal fragment should be small, so that the screw will gain a firm hold.* With a screwdriver I then drive the screw down until the parts are firmly together—sometimes using two screws, sometimes one. I do not usually attach fine wires to the screws to enable me to find them. The screws as a rule are gradually forced from their beds by the reparative process, and can usually be picked from the surface of the bone after two months. I rarely need more than a pair of dressing forceps to remove the screw. After it is removed, the sinus, which has persisted throughout the entire course of treatment, soon closes without any evidence of partial necrosis that would be supposed to follow the use of the screw.

The following case well illustrates the combined use of the screw and wire:

I. S., a colored man, came under my care four months after injury. He had been treated for fracture of the inferior maxilla to the left of the symphysis, a fracture of the ascending ramus remaining undetected. When he came under my care the posterior line of fracture had united with considerable upward displacement, but there was no union at the symphysis. In attempts to close the jaws a single tooth was all that could be utilized, owing to the elevation and overlapping of the fragments.

I operated by an incision exposing the line of union along the perpendicular ramus, and separated the fragments by means of a chisel. A strong wire was then passed through a hole made in the loose fragment (see Fig. 14), thus enabling my

FIG. 14.

colleague, Dr. Hearn, to drag it into position. It was then secured to the perpendicular ramus by means of two screws. The anterior fragments were then approximated and wired. Having bored holes through the jaw on each side the line of fracture, I passed a piece of doubled wire through and made an eye of each, as in Fig. 15. Through these eyes or loops I passed a few short wires, and, drawing these tightly, I twisted them over other transverse wires (Fig. 16). I was then ready to secure the fragments, and, while these were forced into position, I took the free extremities of the wires and

twisted them firmly. I thus secured the fragments, and the result was a useful, presentable jaw. Fig. 17 represents the concluding steps of the operation—which, with modifications, I have repeatedly employed.

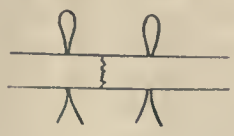


FIG. 15.

FIG. 16.

FIG. 17.

In all my operations, where free drainage has been maintained, I have had a minimum amount of inflammation. In one case abscesses formed in the surrounding connective tissue owing to failure to establish early, efficient, dependent drainage.

THE DIETETIC TREATMENT OF SOME IMPORTANT NEUROSES.

BY JOHN FERGUSON, M.A., M.D., L.R.C.P. EDIN.,
DEMONSTRATOR OF ANATOMY, UNIVERSITY OF TORONTO MEDICAL FACULTY, AND LECTURER ON NERVOUS DISEASES.

IN the year 1882 I began a series of examinations of the urine in health and in disease, and under varying conditions of rest and work, from that of moderation to that of excess. As I have already published my observations on the urine under the different conditions of rest and work, including mental work and anxiety, I shall on the present occasion take up only those observations that lead to valuable suggestions in the treatment and management of some of those important neuroses that are sometimes called functional, but which, I think, should be called nutritional, and, in not a few cases, toxic, in their true character.

When I speak of toxic, I mean that from time to time there is formed within the system, as the result of a derangement of the relation between the processes of formation and elimination, some of those chemical compounds that, when in the blood in greater than the normal proportion, give rise to changes in the action of the nervous elements that become evident by symptoms of a very pronounced nature.

The fact that megrim, chorea, epilepsy, hysteria, the forms of insanity affecting the younger members of society, are ever on the increase, points to some cause or causes that are constantly and progressively with us. These causes, acting steadily, become confirmed in the family history, and ultimately ascend in importance and strength to be true diathetic conditions that may run on through a great many generations. We might mention, as examples, the existence of gout, megrim, epilepsy, etc., that weave themselves so closely into the histories of some families. In a paper of mine, some years ago, I showed how the habits of life of some persons in certain places had developed a tendency to phthisis and to kidney diseases. My present object is to show that certain habits of food and occupation have developed a large and important group of neuroses that, once called into existence, baffle the skill of our best therapeutists.

The more specialized and highly evolved any organ is, the more likely is it to become influenced by unfavorable conditions; the highest functions show signs of failure sooner than the lower and simple functions. Thus it would be that under conditions that cause a departure from the standard of true health the more voluntary would fail before the less voluntary. It would be that side of our nervous nature that is least firmly established or organized, that would become unsteady in the discharge of its functions, and, departing from the average, would be regarded as diseased. Again, those parts of the human body that have the most complex work to perform can be most readily perverted or arrested during the course of development. When each individual is born there is given to the new being a certain impetus, a certain momentum, to carry it on into the future to complete its growth and development. Now, there may be inherited tendencies either to prevent or to arrest. These tendencies, that we are pleased to call inherited, had once a beginning—in other words, were acquired at some date in the past. All this is well seen in the fact that some families are for generations prone to dyspepsia, others to heart trouble in some form, others to hysteria and allied affections, and still others to such a state as pseudo-hypertrophic paralysis. While these cases are admitted as true beyond any shadow of doubt, there is still another direction in which heredity is shown, but which is not yet so well understood, namely, that of the minute chemical composition of the body, and the hereditary tendency to variations in it. The long-continued use of a certain line of diet stamps certain characteristics of composition on the solids and juices of the body that, though minute, are very potent. This we see in gout and in rheumatism, in the occurrence in families of bromidroses, and in the existence in others of hyperacidity of the urine. This is chemistry in its hereditary aspects.

Suppose, now, that within our bodies strychnine was formed, and suppose anything altered the adjustment of formation and elimination, so that this powerful agent accumulated within the body. Tetanic spasms would then result. Or, suppose that the animal economy daily produced a certain quantity of opium, and that this formation continued to go on in excess of its discharge. A state of increasing coma would ensue. But, within our bodies there are naturally formed both convulsants and soporifics—such materials as will produce spasm on the one hand, and coma on the other. We are all familiar with uremic coma; but perhaps all are not equally familiar with the convulsive movements due to an excess of uric acid in the circulating fluids of the body; and yet such formation takes place. It is to this question that I wish to devote some attention, as it is one of much more importance than has been generally thought.

With regard to uric acid in the blood, I am quite in accord with the work already done by Dr. A. Haig. An excess of this agent can act as a direct exciting cause to convulsive attacks. I have for a long time had under treatment a well-developed gentleman, now in his thirty-third year, who has had epilepsy since an attack of inflammatory rheumatism in his seventeenth year. I have often examined his urine, and always find a deficiency of uric acid before attacks, an excess during and just after an attack, and then a deficiency afterward again. To put this to the test, I have on several occasions told him to eat meats, canned salmon, lobsters, cheese, and eggs freely, and to drink ale, beer, or stout at meals. As the direct outcome of this the epileptic attacks became more frequent and prolonged, the primary pallor of the surface more distinct, the convulsive movements stronger, the subsequent paralysis greater, the after-sleep and headache more intense, than when care was taken to use less meat, and no beer or ale.

The lessons from a case like this cannot be lightly passed over. Here is an instance in which certain articles of food and drink have a direct influence upon the attacks. Whether it is that the ingestion of so much nitrogenous food produces an unstable condition of the central nervous matter, or whether the attack depend upon the excess of uric acid thus formed, is a little difficult to determine. One thing, however, remains clear, and that is the advice to reduce to a minimum all nitrogenous forms of food. The case is cited as an example, but I have a number of epileptics that have been greatly benefited by allowing them no animal food, except milk, and cutting off from their dietary all wines and beers. In this way they have been able to get on with much smaller quantities of the bromides; and this has also proved another advantage, as we all admit that the prolonged use of bromides is not devoid of evil.

I cannot say that all epileptics are victims to an excess of uric acid retained within the system. This could only be decided by experience with a large number of cases and as the result of many observations. But, be this as it may, there is now no doubt whatever in my mind that the rigid restriction of the diet, in the manner indicated, will be found a means of much help in the treatment of this class of patients. Connected with this view of the case I found epilepsy frequently associated with a history of rheumatism and gout, either in the patient or in the family to which he belongs. For this reason, along with the bromides, I have often combined the salicylates to wash the uric acid out of the system, and at least relieve this source of irritation. As I have previously said, "I would not go the length of asserting that epilepsy is a food-diathesis, yet I am strongly inclined to think that it tends that way." There is a variety of nervous economy to which certain lines of food prove injurious, and I think epilepsy is a good example of this.

In hysteria I have often found an excess of uric acid in the urine at the time of the attacks, but I have not made a sufficient study of these cases to venture any positive opinion. On the allied condition of neurasthenia, however, I have no doubt but that the uric-acid condition has considerable influence. The lithemic condition has often been noted in these cases, but whether to regard it as cause or effect has remained in doubt. The greater the quantity of uric acid excreted in the urine per diem the greater will be the degree of the depression, or neurasthenia. The brain is very anemic, and as a consequence badly fed. It is not only starved, but in addition it is poisoned. It is in this way that we can account for the despondency and melancholia of this class of sufferers. I have now the record of a large number of observations made on the urine in such cases, and just in proportion to the excretion of uric acid is the depression or neurasthenia.

In the treatment of these cases I have been led to depart a good deal from the plans usually adopted. The patient is at once placed upon a milk and farinaceous diet. All stimulants in the form of wine, beer, etc., are strictly interdicted, and rest and quiet are advised. The patient is then ordered opium in solid form in doses of from gr. ¼ to gr. 1, three times a day. Great care must here be taken that the patient knows nothing of what is being given; as soon as the stage of depression is passing away, the dose of the opiate is to be lessened until it is wholly withdrawn and a tonic is substituted for it. In the meantime put the patient on a mild

course of the salicylates, and maintain this until the excretion of uric acid is reduced to the normal. Should massage and electricity be required to recall lost energies, by all means use them, but not until the foregoing plan has been tried for some time.

The use of opium in these cases is very helpful. It produces a feeling of ease and comfort in the patient that aids the other means of treatment. In addition, it affords the system a much-needed rest. I mean more than a mere physical rest. There ensues a quiet to all the functions, and an arrest of waste, that is very much needed in all these cases of neurasthenia. Under the influence of the judicious use of opiates the patient's attention can be withdrawn from the habit of introspection to take a wider interest in outside affairs. In other words, the patient thinks less about herself or himself and more of other things. In the meantime, by a properly regulated diet and the use of the salicylates the uric acid that has usually been accumulating for a long time is washed out of the system. The limitation of the food to milk and farinaceous articles steadily improves the appetite. Some of the mineral waters, as Frederichshall or Carlsbad, are decidedly useful in clearing the system.

A few words on chorea. The value of arsenic is fully established in this disease. It often fails to do all the good it might, because it is not given freely enough. This drug must be pushed to the full point of tolerance; when it is necessary to leave it off for a day or two begin again with the full doses that were given at the time of the interruption. But, as I have made several examinations of the composition of the urine in this disease, and have found an excess of uric acid present, and consequently in the blood during attacks, it has been my custom, along with the arsenic, to give the salicylates. This has another explanation in the fact that chorea so often occurs in persons with a rheumatic history. Potassium iodide has, in my hands, sometimes been very useful, especially if there are any cardiac symptoms. Another drug that is not used in chorea nearly so frequently as it merits is opium or morphine. A hypodermatic of morphine given to a patient twisting around with choreic movements will convince the most skeptical as to its value. The movements should be nearly controlled by the opiate, and abundance of sleep secured by the same means. A thoroughly nourishing diet of milk and farinaceous food must be pushed freely, in order that the tone and strength of the patient, which are low, be made up with the utmost speed.

I now come to the last disease I intend touching upon at this time, namely, megrim. I wish to enter my unqualified protest against the terms "bilious sick-headache," "dyspeptic headache," and all such names as would lead to the belief that the attack of headache is due to mere indigestion. Nothing has done more to retard true pathology and therapeutics than the prevalence of such a view of these attacks.

To begin with, I have not found a single case of megrim that has not been a pure diathetic condition. I am perfectly prepared to stand by the assertion that true megrim is a lithemic crisis. This state causes the hard pulse, contracted arterioles, headache, vomiting, and finally the regurgitation of bile into the stomach and its rejection by the mouth. I have patients who will pass an entire year without a single attack, provided they watch their diet. Meat, cheese, eggs, and fish with red flesh, I order them to abstain from, and to use no wines or beers. So long as this advice is followed all goes well.

The treatment of these cases resolves itself into two parts—that of the attack and that of the diathesis. First, then, as to the attack. The patient calls for relief. If the attack is seen early a full dose of phenacetin, or antipyrin, may be ordered, and repeated if necessary. These agents, however, are not always sure to succeed, and the pain goes on, uninfluenced by them. Vomiting may ensue, and prevent the action of any medicine given by the mouth. Now, there is no need for this failure. Give the patient a hypodermatic injection of morphine, and rest, and ease will soon follow. The objections to this treatment are that there is pain after the morphine ceases to act, and that a morphine-habit may be contracted. Neither objection holds good. Give salicylates freely while the patient is under the influence of the opiate. By this means the uricemia is got rid of, and the angio-tetanus removed. This being the case there will be no further return of the headache. There is no danger of forming a habit, when we bear in mind that with proper treatment the attacks will practically cease.

The treatment in the intervals of the attack is the main point to which attention should be given. The uricemia must be corrected, and to this the attention must be steadily directed. I maintain that if patients will only live up to the information we are able to give them, they may have the control of their attacks of megrim in their own hands. By the complete denial of all ale, beer, porter, etc., and of all kinds of wine, and absolutely refusing all animal food, except milk, the diathesis on which it depends must entirely disappear. Just lately a lady consulted me for attacks of headache, which she said always occurred on the right side. She had often had slight experiences of muscular rheumatism, and sometimes she had had pains in her small joints, particularly in those of the fingers. Her family history showed the existence of rheumatism. Her daughter, just eleven years of age, is quite subject to migrainous paroxysms. There are no ocular

defects. The mother complains of feeling very languid in the mornings, and brighter in the afternoons and evenings. This is very typical. She says that she has been a free meat-eater, and that while nursing, she drank a good deal of beer and ale. This is a sample of many others.

There is one point to which I would specially call attention. It is that, just before an attack of megrim, and during the early period of the attack, there is almost invariably a very abundant passage of urine of low specific gravity and high acidity. From this feature alone many of my patients can tell that an attack is coming on, and can ward it off by a full dose of opium and the free use of the salicylates. The reasons for this line of treament I have already given.

Another striking feature of megrim is that patients so afflicted have usually morning headache. I have at the present moment before my mind a number of these cases. This morning headache passes away by noon, and the afternoons and evenings are usually spent comfortably.

In the case of children with headache while attending school, there is always a very noticeable irritability of temper. This irritability of temper and headache can frequently be shown to be connected with an excess of uric acid in the blood, and I find it just as frequently yield to a course of salicylate treatment, and the use of milk instead of meat.

One clergyman, now the principal of a college, told me that he would often not have been able to go through with his services on Sabbath had it not been for a free glass of acid sherry wine. Here we have the whole solution in a nutshell. The acid wine, for the time being, reduced the amount of uric acid in the blood, precipitated it out of solution, relieved the tense, hard pulse, gave the brain more blood, caused a free flow of urine, and enabled him to discharge his duties.

HYPERTROPHIC CIRRHOSIS OF LIVER.

With Report of a Case and Autopsy.[1]

BY HUGH B. MEREDITH, M.D.,
FIRST ASSISTANT PHYSICIAN TO THE STATE HOSPITAL FOR THE INSANE, DANVILLE, PA.

WHILE the clinical history and morbid anatomy of this rare form of chronic interstitial hepatitis may have been described as an anomaly occurring in the ordinary form of atrophic cirrhosis, it was not differentiated as a distinct disease until within comparatively recent years. To the French is due the credit of its recognition. The first mention as such was by Hanot in 1875, who reported a case of "hypertrophic cirrhosis with chronic jaundice." In the following year Charcot set forth its essential character so faithfully as to give rise to the appellation "Charcot's cirrhosis of the liver." Many English writers, however, are disposed to dispute its existence as a distinct form, and attribute the enlargement to fatty or amyloid infiltration. As exceptional complications, enlargement of the liver from these causes may occur in Laennec's cirrhosis, but the morbid change is characteristic of fatty or amyloid liver rather than of sclerosis, and bears no relation to the disease under consideration.

Professor Loomis, in his *Text-book of Practical Medicine*, as late as 1884, says: "There is a form of interstitial hepatitis that has been called hypertrophic cirrhosis, because the liver is markedly increased in size, sometimes reaching six or seven times the normal weight. But the fibroid change, the yellow staining, the atrophy of liver cells, the fatty change at the periphery of the lobule, are the same as in the ordinary variety, *the only difference being a marked increase in the size of the liver.*"

One source of error has arisen through failure to distinguish it from the first stage of atrophic cirrhosis, which is also characterized by enlargement. Macroscopically, should death afford an examination of the liver in the early history of the disease, the two affections might be confounded, but when pursuing their usual course, the atrophic form eventuates in diminution in size of the liver, while in the hypertrophic the enlargement progressively increases and always remains until the patient succumbs. Aside from the increased size of the organ, the clinical history is so widely at variance with that of atrophic cirrhosis as to imply a distinct disease, even were the pathology and etiology the same.

The degree of obstruction to the portal circulation is a discriminating point. Hyperemia of the gastro-intestinal mucous membrane, hematemesis, severe epistaxis, formation of hemorrhoids, petechial extravasation, enlargement of the internal abdominal veins and establishment of collateral channels of circulation, enlargement of the superficial abdominal veins and formation of the so-called "caput Medusæ," early ascites from increased tension of the portal circulation, with the characteristic globular abdomen so common in the atrophic form—these are wanting, or exist to a very slight degree. Instead of these there is early jaundice, intense and permanent in character, simple anorexia and nausea with constipation, whereas in the contracted liver the discoloration amounts to a slight dinginess or sallowness of the surface, slight yellowness of the conjunctivæ, and the gastro-intestinal disturbances form more serious complications—as nausea and vomiting, ulcerations of the mucous membranes, hemorrhages, diarrhea, and dysentery. The differential diagnosis of the two affections may be summed

[1] Read before the annual meeting of the Montour County Medical Society, June, 1891.

up as follows: In atrophic cirrhosis there is a slight enlargement of the liver, followed by contraction, with more or less nodular surface, early ascites, absence of jaundice, obstruction to the portal circulation, gastric disturbances with diarrhea, and a greater inclination to hemorrhages. In the hypertrophic variety there is progressive enlargement with smooth surface, absence of ascites, early jaundice, becoming intense and general, less obstruction to the portal circulation, less gastric disturbances, more frequent constipation, and little tendency to hemorrhages. In its pathological histology we would naturally expect to find the true differential characteristics. The morbid change is essentially the same as regards the elements; that is, in both forms it consists of hyperplasia of connective tissue, resulting in degeneration of hepatic cells. But the point of election in this proliferation of new material differs. In the atrophic form it has been clearly established that the initial deposit occurs around the radicles of the portal vein in the interlobular spaces, consisting of an infiltration of round and spindle-shaped cells that develop into a fibrous texture, that by shrinking resembles cicatricial tissue. The bands thus formed between the lobules or groups of lobules, are seen ramifying through the liver in various directions, and are still more highly organized by the production within their meshes of newly formed bloodvessels directly connected with the interlobular veins. The blood furnished the hepatic cells, both for nutritive and glycogenic and bile-producing functions, by the hepatic artery and capillary divisions of the interlobular veins, penetrates the lobule at the same point. By compression of these radicles the nutrition of the lobule is diminished or ceases, and atrophy of the cells results. Probably direct pressure of the interstitial deposit upon the periphery of the lobules assists slightly in producing this effect. The remaining healthy cells and those of contiguous lobules undergo hypertrophy, often amounting to two or three times the natural size. Thus, side by side, we have a hyperplastic deposition of connective-tissue elements associated with enlargement of hepatic cells, and a diminution of structure through contraction of new tissue and atrophy of other cells, producing in the progress of the disease either hypertrophy or atrophy of the whole organ according to which process preponderates. The interlobular bile-ducts survive the destruction of their respective lobules.

These changes in structure would necessarily produce obstruction of the portal circulation, while the bile, although decreased in amount through loss of secreting surface, is carried off in the usual way.

In hypertrophic cirrhosis the opposite condition prevails. The deposition of interstitial connective tissue has its origin in the radicles of the interlobular bile-ducts. According to French writers, "although no obstruction of the secretion nor inflammation can be demonstrated in the larger bile-ducts, the interlobular canals become dilated and ramify into finer ducts, forming immediately in front of the margin of the lobule a network from which still finer branches proceed, to disappear between the hepatic cells." This capillary network naturally lies within the peripheral zone of the lobule, but by atrophy of surrounding cells appears upon its margin and might be mistaken for newly produced vessels. "All these canals are lined with cubical epithelium; in the ultimate divisions the caliber often appears to be plugged with this epithelium. In the vicinity of these canals the indications of this new formation of connective tissue are the most distinct." "Hanot, as well as Charcot and Gombault, base upon these appearances the theory that in cases of hypertrophic cirrhosis accompanied with early jaundice the primary lesion consists of a (spontaneous) inflammation of the interlobular gall-ducts induced by some unknown cause, and that the interstitial proliferation takes its start from the walls of these ducts."[1] Frequently the process extends to the intralobular ducts, and minute bands of fibrous tissue are found penetrating the lobule well into its interior. Unlike the other forms of chronic interstitial hepatitis, the distribution of the new product is more regular, giving the cut surface a uniform appearance in color and consistence.

As the portal circulation is not extensively interfered with, the cell-degeneration through nutritive changes would be small as compared with that found in the atrophic form, and that that does occur is mainly due to pressure upon the periphery of the lobule. Likewise, for the same reason, the total amount of blood in the organ is but slightly diminished, although through increase of size there may be apparent anemia. The bile-secreting function is also less impaired, but by occlusion of the biliary radicles the bile remains in the lobules until absorbed by the bloodvessels and deposited in other tissues as a general icterus. The increase in size as compared with the atrophic variety is thus due to additions of connective tissue without a corresponding degree of cell-degeneration, less diminution of blood, and greater accumulation of bile.

With these preliminary considerations I have to report the following case that I deem of interest, as I have been able to find but two other cases reported in this country, one by W. Osler,[2] and

[2] "Cirrhosis of Liver with Enlargement, No Ascites, etc." Montreal Gen. Hosp. Path. Reports, 1877, i, 56–60. Also reprinted in Canada Medical and Surgical Journal, Montreal, 1877, vi, 249–253.

another that occurred in the Massachusetts General Hospital.[1]

R. A. McC., female, aged sixty-nine, a native of Ireland, resident in the United States twenty years, the widow of a banker, was admitted to this hospital October 15, 1890. Her husband has been dead about twenty-five years. She has no living children, and she has had one miscarriage and several abortions. The history of the case is meager. She appears to have been more than ordinarily intelligent, of good family, rather fond of the good things of life, and from her own statement accustomed to alcoholic beverages, but to what extent was not satisfactorily ascertained. She says her father died, aged eighty, as also her mother and one brother, of phthisis. There was no hereditary neurosis, syphilis, gout, or rheumatism discovered. She was about the average height, slender frame, probably in health weighing 125 pounds.

On admission she was much emaciated and physically badly impaired, the pulse 108, full and regular. The heart-sounds were normal, the tongue dry and red in the center, the bowels torpid, facies dejected; memory for distant events fair, for more recent ones apt to be faulty. She was deeply jaundiced over the entire body. The liver was enlarged, as was evidenced by the increased area of dulness and the rounded edge felt below the line of the ribs, and it was slightly tender on percussion. There was no ascites or enlargement of the superficial veins, and the abdomen was rather flat in dorsal decubitus. The lungs were normal. The left leg was edematous, the right helpless and painful at the hip-joint, attributed by her to a fall sustained about ten days previously, but by authorities to an apoplectic stroke, for which there is now no visible proof. There are excoriations on different parts of the body, due to want of care. She is weak and entirely helpless, and was carried to the hospital on an improvised stretcher. The previous history was uncertain, but friends state in a general way that she had been ailing for two or three years and that jaundice had existed about a year.

The urinary analysis was as follows: Quantity diminished, color brownish-yellow, reaction acid, sp. gr. 1016, the odor offensive, with a heavy white deposit. It contains a large amount of bile, the existence of albumin not satisfactorily determined, but thought to be present. Microscopically it shows bacilli, pavement and round epithelial cells, a few leucocytes, granular matter stained yellow, a few granular casts, and leucin crystals. She was ordered nitro-muriatic acid, gtt. v, t. d., and a diet largely milk and soft farinaceous articles, with lean steak and eggs.

On November 8th, no marked change had occurred. The pulse was full and strong, the appetite capricious, the icterus continuing unabated. She complained of fulgurant pains in different parts of the abdomen and of looseness of the bowels (a false impression occasioned by tenesmus, the condition being in reality one of constipation). The edema of the limb has disappeared, and she has partially regained the power of the injured one. She remained helplessly in bed. On December 13th, the physical condition was somewhat improved and she was disposed to help herself. She was still deeply jaundiced, color of varying intensity. The bowels were kept regular by one-drachm doses of Rochelle or sodii phosph. once daily; the stools were clay-colored, of putty-like consistence, and much compressed from constriction of bowel. There were abdominal pains of paroxysmal character, lasting from three to four hours, which usually came on toward morning, and referred to different points. Pruritus was very annoying, and small abrasions have been caused by scratching. There was no dropsy. On January 20th, the jaundice had increased, some days the skin assuming a bronzed tinge, due probably to changes in the activity of the renal elimination. The bowels were unchanged, save that she passed small quantities of blood with the stool and complained of hemorrhoidal pains. There was tenderness on palpation over the entire abdomen, but this was most marked in the left lumbar region. She had pain in the groin and generally throughout the abdomen, with cramp-like paroxysms at irregular times. There was no ascites, but slight tympanites had developed. Pulse 84, full and bounding, but easily compressible; superficial veins somewhat distended; previously these veins were entirely emptied by slight stroking and were seen to very slowly refill, showing the low tension of the venous system. The tongue was clean, smooth in the center, and moist. The appetite was failing, and slow emaciation was going on. There were profuse sweats during sleep. On February 22d, the most noteworthy feature of the past month had been accession of a mild fever resembling hectic, the morning registration being 99.4°, the evening ranging between 100° and 101°, patient often mentioning chilly sensations. She had frequent slight epistaxis. On March 14th, enlarged lymphatic glands in the right groin were noted. A distinct tumor was now found occupying the right lumbar and inguinal regions, having a well-defined, rather sharp border anteriorly. Percussion elicited superficial dulness with deep tympanitic resonance, continuous with the line of the natural liver dulness. Occupying the exact position of the cecum and ascending colon, it had somewhat the appearance of a fecal accumulation. The bowels were moved regularly by means of laxatives. There were no gastric symptoms, but she complained of constant cramp-like pains in the epigastrium, probably due to pressure upon the solar plexus by the enlarged liver. There was no special pain or tenderness in the liver itself. From this time to April 25th, typhoid symptoms increased *pari passu* with the liver degeneration and diminished vitality, the temperature ranging between 99.5° and 100.4°. Subsultus with increasing hebetude were attending phenomena. There was no change in the icterus and character of the dejecta, and no hemorrhages. She complained of pain in the rectum; occasional nausea, no vomiting; feet becoming edematous through general debility, the liver steadily increasing in size. On May 3d, after an unusually restless night, she was

[1] A. L. Mason: Boston Medical and Surgical Journal, 1886, cxv, 281.

found with a pulse of 102, full and compressible, an axillary temperature of 102°, the bowels constipated, notwithstanding the usual laxative dose. She showed increasing signs of mental hebetude. On May 5th, the stupor was increasing and it was now somewhat difficult to attract her attention, but when aroused she answered questions. The stomach was still irritable, rejecting much that she took. She complained if moved or touched. Death occurred on May 7th.

Autopsy—seven hours after death. This showed that the body was greatly emaciated, probably weighing ninety pounds, intensely and uniformly jaundiced, the skin smooth and soft. The abdomen was much distended and tympanitic over the whole surface. A deep dulness obtainable over the right hypochondriac and lumbar regions. The lower border of the liver readily felt on palpation some distance below the line of the ribs. On opening the abdominal cavity, its walls and the omentum were found devoid of fat, the bowels much distended with gas, empty of solid material, normal in appearance, except the entire sigmoid flexure and most of the descending colon, about 1½ feet of bowel, which was evenly constricted and its coats much thickened; opened longitudinally, it measured from 1 to 1½ inches transversly. This change was evidently the result of an old colitis and explains the very attenuated character of the stools. There was no dropsical effusion in the peritoneal cavity.

The liver was much enlarged, extending downward into the right lumbar and across into the umbilical region. The lower edge of the right lobe occupied a line on the right drawn from the center of Poupart's ligament to the umbilicus, thence upward to the epigastrium, and across toward the left hypochondriac region. The lower edge of left lobe was sharp, while that of the right was more rounded and smooth, the natural contour being but slightly altered. The gall-bladder was much enlarged, and contained about 4 ounces of thin bile, without concretions. The weight of the liver and empty gall-bladder was 76 ounces. The capsule was somewhat thickened, and in places slightly adherent. There were also slight adhesions with the diaphragm and between the gall-bladder and bowel, showing an old peri-hepatitis. The surface was smooth or very finely granular, the color of the surface being not unnatural. The liver on section cut hard, the structure was dense and had the appearance of an extensive deposit of fibrous tissue evenly distributed throughout the whole organ. It was rather anemic and slate-colored. Patency of the common bile-duct was not determined. The kidneys were enlarged to 7½ ounces, the capsule adherent in places and showing somewhat the same degeneration as the liver. The spleen weighed 10 ounces and was considerably congested. The stomach was somewhat dilated with gas, but there was no evidence of gastritis or engorgement of vessels. The intestinal tract was also healthy, except as above stated. The mesenteric glands were not enlarged, and there was no evidence of engorgement of any abdominal bloodvessels.

From the general condition found, it is evident that the disease of the liver was one of hypertrophic cirrhosis.

I am indebted to my colleague, Dr. A. R. Elliott, for notes of the last few days of clinical history, and the post-mortem examination. Through inadvertence specimens were not saved for microscopical examination.

The various affections that might be mistaken for hypertrophic cirrhosis because associated with enlargement of the liver, are amyloid and fatty degeneration, cancer, and hydatid cysts. Amyloid degeneration is also characterized by an equal enlargement of the liver, smooth surface, firm, hard, resistant feeling, and a like enlargement of the spleen. But the edges of the liver are sharp, the affection is a painless one, jaundice is absent—the skin being pale and leukemic instead—amyloid degeneration of other organs occurs, and etiologically there is a history of syphilis, prolonged suppuration, or disease of the bones. Fatty liver does not attain the same size, has rounded margins, smooth surface, is soft and flabby. There is no splenic enlargement, an absence of jaundice, the skin shining with fat, and velvety. There is a disposition to fatty deposits in other organs, and no abdominal tenderness. There is a history of alcoholism, long-continued wasting diseases, and high living with sedentary habits. Cancer is accompanied by tenderness of the liver, hard nodular enlargement, giving it an irregular shape, more rapid development, cancerous cachexia, and frequently in the latter stage jaundice and ascites, an hereditary predisposition, and is usually secondary to cancer of other organs. Hydatid cysts present few of the symptoms of hypertrophic cirrhosis. The enlargement is nodular, large, smooth, soft and elastic, and without pain. The peculiar hydatid fremitus is sometimes obtained on percussion. By use of the exploring-needle a saline fluid, containing the hooklets of the echinococci, may be withdrawn, which settles the diagnosis.

The early stages of hypertrophic and atrophic cirrhosis cannot be distinguished from each other, but, as already pointed out, in the former variety as the enlargement progresses a destructive train of symptoms supervenes. In both varieties the inception is so insidious that remedial aid is not sought until the characteristic changes occur. The etiology does not differ essentially from that of the atrophic form, since in the majority of cases alcohol is the prime factor. Long-continued malarial affections, and certain infectious diseases—as typhus and cholera—predispose to the affection.

As regards prognosis, the disease when fully established is always fatal, after running a course of from two to five or more years, the termination usually being by asthenia, but frequently ending in a

typhoid state consequent upon toxemia. Convulsive seizures are not unlikely to occur.

The treatment is usually based upon the expectant plan—that is, the physician expects the case to die, and is seldom disappointed. For a systematic treatment the same remedies have been advocated that are used in the atrophic form—the iodides, mercury, muriate of ammonia, arsenic and iron.

In atrophic cirrhosis Semmola[1] regards an absolute milk diet as a positive remedial measure of undoubted curability, provided the regressive processes have not advanced to any great extent, and he even claims a diminution in severity of all the symptoms after such change has become thoroughly established. As the fundamental histological change — hyperplasia of connective tissue—is the same in both affections, the same benefit might be expected in the early history of the hypertrophic form. At any rate, as the principal indication is to maintain the general nutrition unaided by the function of the liver, we have in milk, if not too rich in fats, an easily digested article worthy of trial.

In the case reported, the measures adopted were: acid. nitro-muriatic. gtt. v–viij, t. d., during the first months; small doses of Rochelle or sodii phosph., artificial digestants, milk and farinaceous diet, with lean beef, fresh fish, and eggs. Small and infrequent doses of morphine were given to relieve pain when unbearable, and whiskey when the vital powers urgently required stimulation: manifestly a sustaining treatment, rather than one directed against the progress of the disease.

MEDICAL ETHICS GONE TO SEED.

By JAMES H. BELL, M.D.,

FORMERLY DEMONSTRATOR OF ANATOMY IN JEFFERSON MEDICAL COLLEGE; MEMBER OF THE OPHTHALMOLOGICAL STAFF OF THE OUT-PATIENT DEPARTMENT OF JEFFERSON HOSPITAL; OPHTHALMIC SURGEON TO THE SOUTHWESTERN HOSPITAL AND DISPENSARY, PHILADELPHIA.

MUCH has been written in praise and in censure of our system of medical ethics. The question of the effects of the code on medicine and medical character has been so often brought up for discussion, either in the way of attack or defence, that it seems almost a waste of time to make it the subject of an additional essay. But the present wide prominence and damaging effects of certain misconceptions and practices arising out of these relations, and the great practical importance of forming a right estimate of them, would appear to demand a further, and continued, participation in their treatment.

The basis and general character of all discussion upon this fruitful theme are, curiously enough, comprehended in the general belief that medicine is practised under the dominion of a code of ethics and that the code is so universally, wisely, and impartially operative, that it is effectively employed in the redress of great wrongs and in the necessary defence of great rights, whether of persons or of principles, involving the welfare of medicine and of medical men. This flattering and partial view of the extraordinary power and efficiency of the code is based on the assumption that its provisions governing individual conduct are rigidly enforced. As a matter of fact, however, the code is nothing more than a kind of authorized creed, expressing, in fair language and spirit, the assumption by a class of certain moral and protective privileges and responsibilities. It dwells upon the physician's duty to his patient, to himself, his professional brother, and to society at large. It urges him to observe, in his professional walk and conversation, those higher graces of manner and feeling that in social life are the distinguishing marks of culture and refinement. It is pronounced, too, in its disapprobation, intolerance, and proscription of this and that and the other thing. But there are no powers in the code back of these visionary pronunciamentos that have the effect of sensibly influencing professional conduct at the present time. This, in a word, means that subscription to the code does not necessarily influence subsequent behavior, does not prevent a man from pursuing his own particular business in his own particular way.

It should be observed, perhaps, in this connection, that the successful operation of a law, or system of ethics, depends on more than the mere ability to punish violations of its provisions. It depends very largely on the intellectual and moral susceptibilities of the individual units composing the class it is designed to affect; and the character of the individual units in these provinces of the mind, is the result of primal and determining influences widely varying and remote, and comprehend man in all the relations of life. Men do not live and act and feel by generalized rules, and it does not appear to be in the economy of Nature, or rather it should be said in the economy of man, to devise a system of rules that shall compel men thus to live and act and feel. In the family government, where the conditions for their successful employment would seem most favorable, such rules are partial failures, or even something worse. The switch and moral suasion, used separately and in supposed judicious combination, have been tried in vain to subdue the rebel twists of human nature. Law, looking into a larger field, does not prevent the failure of banks, or bank presidents from sailing away to Brazil. The doors of our rumshops are by law closed on the Sabbath day, but

[1] Transactions of International Medical Congress, Amsterdam, 1879.

the "speak-easy" flourishes in perpetual lawlessness, and so on to the end of the calendar, and through all the gradations of crime.

But, as to medical ethics, it should be remembered that the code was originally addressed to a profession that was supposed to be animated by a nearly common intelligence, resolution, and purpose. And the prevailing confidence in the unanimity of medical character and purpose was a partial justification of the belief that the code would be free from the oversights and inconsequences that in the very nature of things would follow an appeal to divided and antagonizing interests. It came into existence, moreover, at a period in the history of medicine when men were qualified by more than professional learning and experience for the practice of medicine. They were also qualified for it by general culture, by temperament, and by habits of life. They were keenly alive to professional questions and interests, entertained enlightened and very decided views concerning the better government of medicine, and opposed every movement that threatened, even remotely, to lower its ethical character. The code was born of this conservatism and devotion to high principle, and deservedly received the earnest and united support of the medical men of the time.

"Quantum mutatus ab ilio"—how changed from that—are the words Wycherly in his old age wrote under the portrait of his youth. We might apply them to the ethical character of medicine to-day as compared with the ethical character of medicine fifty years ago. We are living under a new medical dispensation, brought about by the readjustment of old principles to a new object. And that object is commerce.

It is the high genius and aim of trade, *per se*, to accumulate a large bank balance, to get itself on in the world by any and every legitimate means in its power. This is its proper business. Its vast resources and tremendous energies are engaged in hard-fisted, selfish enterprise. It has no refined sensibilities, recognizes in practice no self-retarding principles. It has no time to dream away in Arcadia. It says boldly, and with the true Gradgrind spirit and emphasis, "The devil fly high with ethics!" This is the case with medicine to-day. The code is obsolete. Its boasted omnipotence and security are attempted delusions. It offers nothing that excites the modern doctor's Yankee suggestion of readiness to take possession of a good thing. It does not create, enforce, or in any way practically sustain a line of conduct that the keen instincts and practices of trade shall respect and observe. It offers, on the other hand, no perceptible or admitted distinction to the man who is, by education and reason and good taste, ethical at heart and in practice. The burdensome vexation of a distinctly commercial purpose and a distinctly selfish personality in medicine have obscured all that was at one time so abundantly and beautifully predominant in the code and in medical character, and made them appear too remote and impracticable for everyday life. And this fact is made practically significant in more ways than one.

The most noteworthy and perhaps culpable departure from ethical consistency, and the one, moreover, that reaches furthest in its bad effects and consequences, was taken, and is even now industriously followed, by the medical schools of the country. I refer to the admission into medical schools of men who are, by earlier education and habits, utterly disqualified to assume the ordinary duties and responsibilities of professional life. And although the general evidences of the bad effects of a course so purely and undeniably selfish and commercial are plainly to be seen, selfishly interested persons will claim that the system is not selfish, or only partially and unavoidably selfish, and that it is the duty of the *State* to obviate the evils indirectly growing out of *illiteracy in medicine* by the introduction of a better system of public schools. This bold attempt to hide the truth under a false issue is what logicians would call a *non sequitur*, a consequence that does not necessarily follow from the cause. It is in truth a play of hide-and-seek with principles they are under some compulsion to outwardly observe. To show the utter fallacy of such conduct and reasoning, it is only necessary to observe that there is no law compelling the medical schools under its jurisdiction to accept all uneducated and feeble-minded persons who may apply as candidates for the doctor's degree. Their management, however, would suggest the operation of some such legal provision. The active cause, therefore, of the death and decay of medical ethics is justly attributable to the management of medical schools, and I venture the assertion that the cause is likely to continue active as long as the question of numbers is of pecuniary interest to those engaged in the responsible work of teaching.

The State may bestir itself and do something in the course of the coming century to check the hatching-out of doctors by the present unnatural and disgraceful process of incubation. It might, for example, exclude from medical schools men whose most labored efforts at correct utterance are murderous innovations upon the purity of the mother tongue, and whose orthography exhibits an utter disregard for monosyllabic propriety. It might even go further, and at once extinguish nine-tenths of the medical schools of the country, by making a rudimentary knowledge of grammar and arithmetic necessary qualifications to matriculation. It is idle to pretend that such an exercise of executive discretion and power, in a matter of

this importance, would be ill-advised or premature. For, in the absence of legal restriction, or like influence for good, we already have a very considerable outcropping of the evils thus bred in the professional bone, showing themselves in subsequent practice under the code.

The declension from once higher ideas, and from the stricter principles of honor and justice, is conspicuously shown in the growing tendency of medical men to advertise themselves. Men that are thus led by what they would doubtless call an "enlightened self-interest" to seek returns more substantial and marketable than the silent applause of an approving conscience, do not hesitate to whisper in the reportorial ear, through the intermediation of some judicious and obliging friend, the results of certain important performances. And it is a noteworthy fact, that the reports of operations and cures that by this road find their way into the daily prints with the performers' names duly heralded, are invariably of this significant character. Even the suggestion of a contemplated jaunt to London, Hong-Kong, or the moon, may, in the hands of an expert, be the means of exciting a very considerable public interest. In some instances it requires as many as a dozen notices, published in a score of newspapers at convenient intervals, to satisfy the public appetite for knowledge of this kind.

In conducting enterprises of this character it is not wise, of course, to expose oneself anywhere "below the level of a vulgar rectitude." However, the risk is inconsiderable, for in advertising, as in other forms of human enterprise, practice tends to a perfection of method; and it not infrequently happens that the well-known objections of the code to advertising are obviated by a resort to methods so adroit as to be absolutely illusive. Of this class is the clever copyist, the compiler of useless and confusing books that distract the reader's mind, impose on his memory, and waste his time. Of this class, too, are the men that overload periodical literature with the reports of cases that every physician treats familiarly, for the ostensible purpose of introducing a remedy already in universal use, or to warn the profession against the longer employment of a treatment that has been, by earlier and common consent, relegated to eternal limbo.

Another signal and comprehensive defect in the ethical character of the medical men of the day manifests itself in a glaring and inconsistent behavior in respect of proprietary medicines and formulas. There is hardly an item in the long list of multifarious traffic carried on by the proprietary man that is not used by, and advertised over the signatures of men whose opinions are somewhere treated with deference and consideration. A new humbuggery in the way of a temporary hanging-apparatus, corn-solvent, liver-restorer, or shin-plaster, has only to spring up in the night to find some medical man up and dressed and ready to serve it. Indeed, it looks very much as though the medical man of the future might be compelled by the exigencies of trade to advertise his fractional existence in the open markets of the world, to be inspected and purchased by the highest qualified bidder of a patent medicine, or else to eat his heart out in some obscure, unknown corner.

But this, it may be admitted, is an extreme view of the case. In one of two or three ways medical ethics of the higher sort are likely to be victorious over medical ethics of the lower sort, but the victory will be a costly one both to the conquerors and to the conquered.

In the first place, the fact that medicine is overridden and disfigured by an indirect, surreptitious, and grasping commercialism is too apparent to be hidden by any amount of sophistry and artificial logic. The main features of the question will, we may reasonably hope, be clearly discussed, patiently analyzed, and their fatal tendencies plainly stated. The effects of such treatment will probably be to bring the "saving remnant," the generous spirits, brave wills and clear heads in medicine, into a closer bond of union for defensive and offensive warfare against trade practices and relations. Secondly, the State government may be forced by an educated public sentiment to place medical education under the ægis of law. Or, thirdly, the evils may be destined to remedy themselves; for, *what will there be left in medicine to tempt the avariciousness of trade when its good character is destroyed?*

No one would attempt to deny the right of medicine to rejoice in its brilliant activities and achievements; but how ridiculous is the cant about its model general government! And what a paralyzing, what a drivelling conceit to claim, in the face of disproving facts that the subtlest influence of distorting prejudice cannot hide, that either the spirit or the letter of the code are observed in practice. The prevailing cry of Ethics, ethics! is like that other cry of "Peace, peace!" heard in the lamentations of Jeremiah, "when there was no peace."

ORIGINAL LECTURE.

THE PREVAILING EPIDEMIC OF INFLUENZA.

A Clinical Lecture delivered at the Pennsylvania Hospital, Philadelphia, December 19, 1891.

BY PROFESSOR J. M. DA COSTA, M.D., LL.D.

GENTLEMEN: This morning I shall show you some illustrations of influenza, exhibiting its different types, and make some remarks upon the peculiar features o

the epidemic of influenza, or catarrhal fever, through which we are now passing.

I shall first take up the case of Captain J. F., a hearty man in appearance, well built and strong, who came from his vessel to the hospital on the 7th of December. He was then sweating profusely, had moderate fever, and suffered with great shortness of breathing. His pulse was 108; temperature 101°; the respirations were 26 to the minute; but notwithstanding the fact that the respirations were only 26, he complained of much difficulty in breathing. In the further progress of the case, it was noticed that the face was flushed, and the dyspnea was attended by pain in the chest and in the back. With this were associated physical signs which did not indicate a pneumonic condition. In truth, upon examination, we found nothing in the chest, except here and there a considerable number of dry râles, with harsh respiration; there was no tubular breathing, and no signs of consolidation anywhere existed; though slight impairment of resonance at the lower part of the right chest pointed to some pulmonary congestion at this place. The expectoration was not blood-colored, and rather free. There was no sore-throat, but a very decided degree of laryngitis was present, as shown by great huskiness and almost complete loss of voice; absolute aphonia was never noticed. The urine was found to contain albumin in small amount and a few hyaline casts.

Here, at once, we meet with some points of very considerable interest. Not to detain you with too much detail, I will only ask you to notice, by this chart, that his temperature steadily but gradually declined, so that by the 13th it was slightly subnormal, and on the 14th it had found its way back to normal; afterward, for a few days, it was again subnormal, though it is back to normal to-day. The albumin and the hyaline casts have disappeared from the urine. The pain in the back and limbs, and the headache, which were early symptoms, left him before long. We may now consider the patient as absolutely convalescent. Before dismissing the case, however, I will examine his heart for you. I notice that the first sound is heard, though it is weak in relation to the size of this man; nor is the pulse strong, though you see what a heavily built man he is. The murmur that accompanied the first sound of the heart, early in the case, has disappeared. This is a point to which I especially call your attention.

The treatment consisted in chloride of ammonium for the bronchial affection; quinine, twelve grains daily, as a general tonic, which has lately been discontinued; the chloride of ammonium being stopped also. The tongue still remains slightly coated. The only treatment now needed will be a tonic; we shall give him one-fiftieth of a grain of strychnine, with two grains of quinine, three times a day. The cough is very slight, but you perceive that when the man talks, his voice is still hoarse; his catarrhal laryngitis is not entirely cured. For this condition we will use sprays. He has been using a spray of chloride of ammonium dissolved in Dobell's solution. This will be continued, and, in addition, if the laryngeal catarrh last, we shall make local applications to the larynx of zinc sulphate, ten grains to the ounce.

We shall now take up Case II. This patient is a Russian, aged about thirty-five. A definite history is difficult to obtain, from our inability to communicate with him. So far as we can make out, he had a previous attack in Russia; he had been ill this time for eight days before coming into the hospital, suffering with headache, loss of appetite, and constipation. The headache was the prominent symptom, and in a day or two after, he had a slight cough. On admission, his temperature was 100°, pulse 82; the respirations were 32; he had a coated tongue. He had no apparent disorder of heart or lungs, though subsequently a few râles were perceptible, scattered through the chest. After he had been in the hospital for a few days he became almost absolutely deaf. He had some sore-throat, but no loss of voice; redness and relaxation were seen in the throat, but no exudation. He had considerable pain in the back and in the abdomen. No albumin was found in the urine, and no tube-casts.

Now, in this case we have a peculiarity to note, to which I shall presently call your attention as being one of the striking features of the present epidemic. This man, who has been for ten days in the hospital, still has elevation of temperature. As you see upon the chart, the temperature ranges near 100°; the highest point attained under our observation was early in the case—101⅖°. It is fair to infer that he has passed with a slightly elevated temperature into the third week of the disease; for the history is that he was, for a week prior to admission, in much the same condition as when he came in. Notice the continued character of the fever, though not a high fever. Notice, also, that the continuous fever has existed with a slightly coated tongue, with poor appetite, with constipation, with languor and fatigue, with headache, but without eruption. Even with the closest scrutiny, we have never been able to detect any eruption of any kind upon his skin. Case II, then, is marked by continuous fever, though the fever is slight; marked by aural symptoms with headache, and also marked by the length of the case and by much general discomfort and prostration.

Case III will illustrate some further points that will serve to indicate the peculiar types of the prevailing epidemic. This patient has also had an illness of two weeks' duration; he is an elderly man, sixty-seven years of age, of good family history, and of good private history. He never had a previous attack; he was taken ill two weeks ago, with pain across the chest and in the abdomen; but no headache. He says that he was very much prostrated at first, and the resident physician adds that, from what he was able to learn, he was almost unconscious. He was admitted with a temperature of 100⅘°, pulse of 100, and respirations 28. There were no very marked catarrhal symptoms, no laryngeal symptoms, no sore-throat, no sweating. He was still complaining of pains in his chest and in the abdomen. The urine was normal. He was placed upon salicylate of cinchonidia, sixteen grains daily, in divided doses, and Dover's powder in small doses at night. He was also given tablespoonful doses of solution of acetate of ammonium every two hours. Under this treatment he has very much improved; the pains are almost gone, and he is less prostrated. As an additional feature in this case, it is to be noticed that he only had an elevated temperature for a few days. Upon auscultation, a few friction-sounds were detected in the left chest, toward the base; there was also some

harshness of respiration, in other words, a slight pleurisy with bronchial catarrh at this point. Now, the breathing there is feeble, but no friction-sound is to be perceived. He also is convalescent.

Before proceeding to a discussion of these cases, let me show one other, which I can briefly dismiss, but which I bring before you in order to make my review of this epidemic more complete.

Case IV is another Russian, twenty-one years of age, also suffering with fever, headache, and with congestion of the lungs more marked than in the other cases, but with no pneumonia. He had, however, and this is particularly why I have brought him in, what neither of the other cases have shown, a distinctly high temperature. Now, I will not go into this case further than to state that the temperature reached $104\frac{3}{5}°$, with a pulse of 100, and respirations 28. But notice this curious temperature-chart. The temperature sank decidedly the day after admission. As we ascertained, the man had only been ill for three days prior to admission; the malady not having begun with a definite chill, but with a good deal of pain in the back and abdomen, also in the chest and in the legs. The temperature, I say, which on admission was so high, was the next morning 102°; it then gradually rose from that again, until on the third evening, forty-eight hours after admission, it had reached $103\frac{2}{5}°$. Then, as you see, comes a long line downward, looking like a crisis, and the temperature drops from $103\frac{2}{5}°$ to $98\frac{3}{5}°$—almost like a malarial attack. After this break no rise occurs of more than half a degree. This case was associated with marked sweating, and I will add that sweating still persists to a slight degree. The physical signs in the chest were never marked; there was some congestion of the lungs, and impaired resonance and many râles in the chest, but no consolidation of the lung.

With these four cases before you—although I could show you a great many more from the ward—let us proceed to consider the striking features of the disease now epidemic that they represent. Let us look at these cases as representing types of the malady; though, of course, what I shall tell you is not based solely on these four cases, but on a very large number that I have seen during the last two or three weeks, here and elsewhere; for in truth, the malady is very widely prevalent.

First, as regards the fever, two extremes are met with: the first is represeated by Case IV, the other by Case II. They are types absolutely dissimilar. Case IV, which you just saw, is marked by extraordinarily high temperature, rapidly declining, rapidly rising again to nearly the same point; then a marked fall and a termination by crisis; the whole occupying about one week. In Case II a continuous fever existed, which was so like typhoid that the question constantly arose, Is it typhoid? These are the two extremes. You will ask me, which of these two extremes is more common in the present epidemic. I answer, Neither. The most common form of the fever process that characterizes this influenza, or catarrhal fever, now epidemic, is represented neither by Case IV nor by Case II, but rather by the case you saw in which the fever was not very high or very prolonged. The temperature is not, as a rule, elevated. The case you saw with high temperature is indeed even more exceptional than the one with continued fever and comparatively low temperature. It ought also to be added that the high temperatures are apt to decline gradually and the case does not generally terminate by crisis, as in Case IV, so that this does not at all represent the average case, which is marked by a temperature without much variation and subsides by lysis rather than by crisis. Before dismissing the very interesting subject of the fever-temperature, let me call your attention to several points associated with it. In the first place, I do not remember in previous epidemics to have seen so many cases, like Case II, of continued fever-temperature, looking very much like typhoid. I could in truth repeat the histories of a number of cases observed during the last few weeks, with headache, with coated tongue, and with low fever, which belonged to the epidemic malady, but without red spots, with constipation, and with nothing of true typhoid about them.

Let me also call your attention to the fact that few of the patients have a distinct initial chill, though chilly sensations at the onset are common. I must also mention a peculiarity of the circulation. It consists in an extraordinary lowering of the pulse late in the disease, though sometimes seen before; a lowering that may show you a pulse in the fifties, most misleading and attributed perhaps to remedies, especially if digitalis has been given, but which belongs to the disease, and not to the administration of any medicine.

Albumin in the urine, with casts, hyaline and epithelial, is observed to be quite a common occurrence. This, too, is rather peculiar. It shows that there is a tendency to renal complication in the present epidemic, which is worthy of more notice than I can give to it this morning. I will only add that I have not found this albuminuria to be persistent. Retention of urine is not rare, especially in elderly persons.

On looking at the catarrhal symptoms, we are struck by the fact that there is infinitely more laryngeal catarrh than is common in the history of epidemic influenza. In the case of the ship-captain whom you saw first, he has not yet recovered his voice; and I have a lady under observation in whom the whole disease after the first few days expended itself on the larynx, and who still has aphonia. I may also add that a kind of aural catarrh is also encountered, attended by pain, deafness, and noises in the ears. These types are, to a certain degree, characteristic of the present epidemic; and we also encounter opthalmias preceding or attending the laryngeal and bronchial catarrh, with its harassing and obstinate cough. A remarkable fact to be noticed is that it is not unusual for the malady to subside with coryza, which may or may not have been present at first, or have been present and disappeared. Again, the catarrhal symptoms transfer themselves readily from one organ to the other. Great disgust for food, coated tongue, anorexia, are common; but intestinal catarrh and looseness of bowels I have not seen as often as in some previous epidemics.

Now, when we come to the other symptoms—the pains, the nervous phenomena, the sweating, the prostration—the present epidemic does not differ from other epidemics, except that, perhaps, pains in the bones and in the chest, and the sweating, are less prominent than in other epidemics, especially the one that occurred two years ago; but the nervous phenomena, the delirium, the headache, and other symptoms simulating

cerebro-spinal fever are fortunately much less common and grave, while the catarrhal form, as already stated, is more common. Yet there are cases showing the nervous system much implicated. I may refer to one I have seen in consultation, in which an old lady lay in a state of stupor on the tenth day, and was aroused with the greatest difficulty, only to immediately relapse into unconsciousness. No albumin was found in the urine, although it was repeatedly tested. There were no signs of delirium, merely absolute apathy and stupor. When spoken to, she replied, but immediately relapsed into stupor. She is a hearty old woman and had previously had good health, although changes in the arteries incident to her age had begun to take place. Great depression and despondency are seen in many cases, especially in old people, whose nervous systems are more depressed by the poison than those of the young. In many of these instances, after the febrile stage is over, the temperature is also depressed, and remains so for a considerable period. The most singular nervous disturbance I have encountered was in an old lady seen very recently with Dr. Allen, in whom the disorder was ushered in by a violent convulsion, the first she had had in her life. Her arteries were very rigid ; the kidneys were sound.

One of the most curious features of the present epidemic is the prevalence of cases that at first glance seem mild cases of rheumatic fever. The joints, especially the wrist-joints, are extremely painful, only very slightly swollen, and doubtfully redder than normal; with the pain, which is great, there is some tenderness. We have two cases of the kind now in the hospital. One had, on admission, the injected eye, the catarrhal symptoms of influenza, with a temperature of 103°, that suddenly dropped to between 99° and 100°. There was a short cardiac murmur, which is disappearing. With the subsidence of the malady the pulse has gone down to 52. The use of the salicylates and quinine proved very beneficial, particularly to the joint pains. In the second, the fever was more continued, though slight; the catarrhal symptoms were marked, the joints very painful. There was no murmur. But under any circumstance the murmur cannot be accepted as disproving the nature of the case, and determining in favor of acute articular rheumatism; for I have already shown you that cardiac murmurs may be present in influenza. It is an interesting question whether these joint cases are due to the poison affecting the spinal centers. The endocardial murmurs mentioned are not, I think, the result of an endocarditis, but are of a functional kind.

The bronchial catarrhs form a very prominent part of the symptoms in the present epidemic, and are very obstinate. There are also many cases of congestion of the lungs, and of deep congestion more manifest in parts, forming a kind of bastard pneumonia. Yet true consolidation is also encountered. At the onset of the epidemic real pneumonia was rare. But now it is not so, and we are seeing the full proportion of this dreaded complication. Pleurisy, too, is encountered.

In this epidemic, as in others, we find influenza intercurrent. I am thus seeing at present, with an eminent colleague, a case in which at the beginning of the fourth week of typhoid fever the temperature suddenly went up to over 104°, catarrhal symptoms and loss of voice showed themselves, and the epidemic poison became most manifest.

I have now given you an outline of the disorder as we encounter it in its varied phases, and have compared, as far as here possible, the symptoms with those of previous epidemics. You will naturally want to be informed if the earnest researches of the last few years, during which influenza has been in many countries so prevalent, has given us any clearer knowledge of its cause. Unfortunately not. The malady is generally assumed to be due to a microbe. But this is but a probable and intelligent assumption; for the microbe has not been found.

The great majority of the cases are light. Yet this epidemic is like all preceding ones, swelling frightfully the list of mortality. The old and the infirm, when attacked, speedily succumb. It destroys the weakly, and extinguishes the vital spark wherever it is flickering. Indeed, people no longer talk of the malady, as a few years since, with the jaunty air of amusement. It is beginning to be realized that a widespread epidemic of influenza is a national calamity.

In conclusion, I wish to say a few words about treatment. Besides advising, of course, what is self-evident, that local treatment must be instituted to relieve the laryngeal and aural catarrh, by the usual means, I ask you to watch the chest most closely. We have dry-cupped some of our patients with most evident relief and benefit. Has any specific been found? is there any treatment that the large experience of the last few years has demonstrated to be akin to specific? I wish I could so state. You know that we live in an age of thought about microbes and microbe-hunting, and it is almost inevitable that our therapeutics should be tinged with the theory of a germ to be destroyed; indeed, you can hardly take up a medical journal without seeing a number of remedies advocated that are to affect the supposed germ. Some of them may do good, possibly, even probably; yet I would not advise you, in treating influenza, to rely upon any remedy solely because it is a microbe-destroyer.

But there is no doubt that our tried friend, quinine, is of value; whether it is because it destroys microbes or not, I cannot say. However, in some cases, when there is a good deal of headache and pain through the body, we substitute the salts of cinchonidia, selecting the salicylate, given in daily doses of from 12 to 18 grains. We must also keep up the action of the skin, and if there be not much sweating, I am in the habit of using the solution of acetate of ammonium with small doses of morphine. In all cases, too, the strength must be looked after, and elderly persons generally require stimulants.

In instances of much pain in the head and aching in the bones and muscles, Dover's powder in small doses is beneficial, and it or codeine also helps the irritating cough. In others, we gave antipyrin or phenacetin, grs. iij, with quinine gr. i, in powder or capsule, every two or three hours, until the pain is strikingly modified. One of my patients has become so attached to this prescription that he carries the capsules with him constantly to have them on hand, for he is thus sure of relief; and the combination also relieves the pains that may continue after the influenza attack has passed away. But phenacetin

and antipyrin are powerful agents, and are only to be employed under the observation of the physician. These are strong drugs, in their way as effective as strychnine, opium, or arsenic, and should not be used except under medical direction.

I will conclude this summary of treatment with the advice to you to look after the heart even in convalescence, and for the cardiac weakness, or the slow action which may persist, you will find no remedy equal to strychnine.

Again, impress upon everyone this rule: Give up early, do not go out too soon. The community that learns this quickest will have learned to avoid much suffering and disaster.

CLINICAL MEMORANDA.

CASE OF ANTE-PARTUM HEMORRHAGE IN WHICH THE PLACENTA WAS NORMALLY SITUATED.

BY F. M. GREENE, M.D.,
OF GREEN DALE, KENTUCKY.

MRS. M., a multipara, was just entering upon her ninth month of gestation, when she slipped upon a piece of ice, partially fell, and in recovering the erect position she felt a sharp, lancinating pain in the left side near the fundus of the uterus. She kept upon her feet for two hours without discomfort, but at 1 o'clock she suddenly felt weak and faint, and while attempting to get into bed syncope came on and she fell across the bed. She remained unconscious for some time, there being no one present save a little son, who could render no assistance. At 2.30 o'clock her husband came in and found her lying in this position and thoroughly chilled. He assisted her to bed, placed hot irons to the extremities, gave her spiritus frumenti, one ounce, and sent for a female assistant.

On the arrival of the latter the patient informed her that her "waters had broken," which, on examination, proved to be blood, and several clots were discovered upon her clothing and bed. I was sent for, and arrived at 4 P.M., finding the patient much agitated and alarmed, the face and lips blanched. She complained of no pain; the pulse was 100, weak and compressible. Examination revealed a large clot in the vagina, which was removed. Hemorrhage had ceased. Palpation showed the uterus moderately contracted, with a slight swelling or enlargement near the fundus on the left side, and which was painful on pressure. The condition of the fetal circulation could not be determined, as the placental souffle could not be heard. The os was dilated to the size of a dollar, the membranes slightly tense and protruding, the vertex presenting. A broad bandage was drawn with moderate tightness around the abdomen and secured.

The patient now rested for an hour and a half. There was little or no hemorrhage, but there was a complaint of great fulness, with dull pain over the enlargement at the left side. Having no Barnes dilators, I proceeded as follows: The patient was placed in position for podalic version, the bandage was loosened, and with the palms of both hands, at first moderate and then firm pressure was made over the uterus. This was continued during three distinct contractions, when the assistant took my place and continued the pressure. The os was now found almost fully dilated, and the membranes were ruptured. During the next contraction the vertex was found distending the perineum. The patient was thus saved from the shock and hemorrhage that would necessarily have followed version. As the head emerged the cord was found coiled once around the neck. The cord was released, but was pulseless and flaccid. A single contraction now completed the second stage.

The infant was placed in a warm bath, and after five minutes no further attempts were made at resuscitation.

The assistant had in the meantime kept up constant pressure, and there had been considerable discharge of blood during the passage of the fetus. The placenta was now found blocking the os, presenting by its maternal surface, and partly within the vagina. I now employed Credé's mode of expression of the placenta. There immediately followed a large clot, of placental shape and very firm. The pressure was now continued for one hour by the assistant, when the bandage was readjusted, half a dram of fluid extract of ergot given, and the patient put to bed. Convalescence was normal.

The constitutional symptoms from loss of blood were greater than the quantity discovered on first examination would justify, and in this respect the case resembled one of concealed hemorrhage. The clot probably caused the unusual swelling over the placental site, and was composed both of fetal and maternal blood. The blood, finding its way between the membranes and walls of the uterus, escaped externally, causing the protracted syncope, during which the child perished. Just previously the mother had felt active fetal movements; afterward none at all.

Although the indications were to bring about immediate delivery, the os was not sufficiently dilated, and hence the delay. Finally, as an excitor of uterine action, pressure was chosen instead of ergot or other ecbolic, and contractions were brought about sooner than could have been done by the latter; beside, pressure has the advantage of being completely under the control of the accoucheur.

FRACTURE OF THE NECK OF THE RADIUS AND BACKWARD DISLOCATION OF THE ULNA.

BY C. G. DARLING, M.D.,
OF ANN ARBOR, MICH.

MR. M., a moulder, thirty-five years of age, short and muscular, in wrestling put out his left hand to save himself in falling. There was a snap as the hand touched the floor, then the forearm seemed to turn backward on the arm.

This in substance is the patient's description of the accident twenty minutes after it happened. The injury seemed to be confined to the elbow, which was not much swollen and was partially flexed. The olecranon process projected far backward and above the line of the condyles of the humerus, while the radius seemed to lie

wholly anteriorly to the humerus. There was free lateral motion, so that the forearm, when not supported, would swing from side to side. The least movement caused intense pain, and as nothing was to be gained by prolonged examination, I at once attempted reduction. This proved not to be difficult, for the head of the ulna slipped readily back into place.

Slight rotation at the wrist now produced crepitus, and there was still some deformity near the elbow-joint. The head of the radius was found in its proper place, but half an inch below there was a fracture that seemed oblique, with the short side of the upper fragment above, while the upper end of the lower fragment was drawn upward.

The fracture was easily reduced, but a proper position of the fragments could not be maintained with the elbow at a right angle. After several unsuccessful attempts to keep the fragments in place, the arm was placed at an obtuse angle—nearly straight. In this position the lower fragment was drawn against the upper by the action of the biceps muscle. Here it was quite firmly held, and dressed with an anterior angular splint and a bandage firmly applied.

If we form an opinion from the number of reported cases, fracture of the neck of the radius must be exceedingly rare. Packard ventures the statement that he knows of no instance in which the neck of the radius was broken by itself. Hamilton says that, uncomplicated, it is exceedingly rare; that he knows of but one anatomical specimen of this fracture. In his work on *Fractures and Dislocations*, he reports three cases regarded by other physicians as fracture of the neck of the radius. Some time after repair had taken place these persons were brought to him for treatment. He states that dislocation of the ulna may be complicated by fracture of the radius, but gives no reference or report of cases. Gant, in his *System of Surgery*, gives one illustration of fracture through the neck of the radius—the Mütter specimen that Hamilton figures as the only one recorded. Dr. Fowler, in *Holmes's System of Surgery*, says that authors differ considerably in their estimates of the comparative frequency of fracture of the neck of the radius, chiefly as a result of the difficulty of making an absolutely certain diagnosis. Stimson, in his complete work on *Fractures and Dislocations*, which covers nearly all references to be found on fractures of the head and neck of the radius, mentions one doubtful case of fracture of the neck of the radius, complicated by backward dislocation of the ulna. He says our knowledge of fractures of the head and neck of the radius is drawn from about a dozen specimens and two or three doubtful cases. Recently he has added to the list one that occurred in his own practice. Dr. Nancrede informs me of an unreported case of fracture of the head of the radius with backwad dislocation of the ulna occurring in his practice.

The case that I have reported was treated as an ordinary fracture near a joint. The partially flexed position was maintained for six weeks; then I began passive movement, and twelve weeks from the date of injury all dressings were removed. It is now five months since the injury occurred; the arm can be extended almost to the normal position, and can be so much flexed that the hand can be brought to the face. Supination and pronation are limited, but are well performed. The angle naturally existing at the elbow in extension with supination is greater in the injured arm, showing that the radius is shortened.

What is the evidence of fracture of the neck of the radius? Crepitus could be produced when the elbow and head of the radius were fixed. Marked deformity was shown when the elbow was flexed and the biceps was contracted, the head of the radius still remaining in place, while the upper end of the lower fragment was tilted upward. There was also slight shortening of the radius after union had taken place.

How may the injury be explained? An examination of the radius of an adult shows a marked angulation at the tuberosity, and also that the neck is the weakest part of the bone. Any great amount of force applied to the lower end of the radius and continued through the contraction of a powerful biceps with the arm in a partially flexed position would cause a yielding at the neck. My patient, in falling, probably threw most of his body-weight on the radial side of the hand, the elbow being slightly flexed; at this moment the biceps contracted, and the result was a fracture. A large part of the support to the elbow-joint was now lost—the radius and the biceps muscle—and the forearm turned backward far enough to produce a dislocation of the ulna.

POLYURIA IN PHTHISIS CONTROLLED BY FULL DOSES OF ERGOT.

BY WM. S. BARKER, M.D.,
FORMERLY ASSISTANT PHYSICIAN AT THE ST. LOUIS CITY HOSPITAL, ST. LOUIS, MO.

H. E., a mulatto, thirty-one years of age, entered the City Hospital November 7th, with well-marked symptoms of pulmonary tuberculosis. No tuberculous trouble could be located elsewhere than in the lungs. Whether the symptom about to be described was due to tuberculous deposit in the kidney or in the neighborhood of the controlling cerebral centers in the fourth ventricle could not be satisfactorily determined. During the preceding October the patient had for the first time been somewhat annoyed by frequent, copious, and persistent micturition. Examination of the urine gave the following result: Acid reaction; specific gravity 1004; no albumin, sugar, or casts. But the quantity of urine voided was very considerable, as the following record will show:

	C.c.	Pints.
Nov. 14–15	5,000	10.0
" 15–16	10,400	20 8
" 16–17	8,200	16.4
" 17–18	10,600	21.2
" 18–19	9,100	18.2
" 19–20	7,200	14.4
" 20–21	6,000	12.0
" 21–22	4,400	8.8
" 22–23	2,400	4.8

The marked and steady decrease of urinary excretion after the 19th was due to the administration of rather large doses of fluid extract of ergot. One c.c. doses were given frequently, about 8–10 c.c. being taken daily. The quantity of urine at once began to diminish, and did so steadily each day, declining from 10 600 c.c. to

2400 c.c. per day, at which latter figure it remained until the dose of ergot was discontinued or was made much smaller, when a rapid rise in the quantity of urine took place. This was again brought well under control by increased doses of ergot. The patient succumbed to his pulmonary affection in a few months. Polyuria existed until shortly before death. The autopsy revealed only pulmonary tuberculosis.

MEDICAL PROGRESS.

Phthisis and Tuberculosis Pulmonum.—In support of the view of the non-identity of phthisis and pulmonary tuberculosis, LANGERHANS (*Berliner klin. Wochenschr.*, No. 42, 1891, p. 1034) has reported a case in which tubercle-bacilli were found in the sputum during life while phthisis was not found after death, and a second case in which phthisis was found after death while no tubercle-bacilli could be found in the tissues or secretions. The first case was in a tailor, sixty-eight years old, who, for two years, had complained of cough of progressively increasing intensity. A week before death, a severe chill occurred, followed by decided dyspnea. The sputum was partly purulent and partly rusty, and contained both tubercle-bacilli and diplococci. At the autopsy fibrinous pneumonia of the upper lobe and of the lower portion of the lower lobe of the right lung, with edema, was found. At the apex there was some slate-colored induration and cicatrization, and a number of light-gray, submiliary nodules. The bronchi were dilated and contained purulent secretion. No ulceration could be detected and no unequivocal tubercles were found. The middle lobe of the right lung was partially atelectatic. The upper lobe was small, shrunken, and dense. On section, slate-colored lines, crossed by dilated bronchi, were seen. At the apex were a number of transparent, light-gray, submiliary nodules. The purulent secretion contained many tubercle-bacilli.

The second case was one of myelitis in a man, fifty-four years old, who presented cough, shortness of breath, moist râles, and blowing breathing. When the autopsy was made, fibrinous pneumonia of the lower portion of the upper lobe and of the adjacent portion of the lower lobe of the left lung, and of irregular distribution in the right lung, was found. In the airless portion of the upper lobe the bronchi were dilated and contained purulent secretion and thickened, caseous masses; the mucous membrane was in places ulcerated. The corresponding pulmonary structure was partly atelectatic, partly hepatized. A large bronchus of the upper lobe was compressed by a tumor as large as a walnut and its lumen obliterated. Other nodules found in the mediastinum proved to be round-celled sarcomata. Tubercle-bacilli were carefully sought for, but none were found.

Two Cases of Traumatic Rupture of the Intestine Successfully Treated by Laparotomy.—JAHODA (*Wiener klin. Wochenschr.*, No. 45, 1891, p. 837) has recorded two cases of traumatic rupture of the intestine in which, in the one eighty hours and in the other twenty-five hours after the accident, laparotomy was performed, with subsequent recovery. The one case was that of a previously healthy man, forty-four years old, who was struck in the abdomen by a wagon. Consciousness was lost. On its return there was intense abdominal pain, tympanites, hiccough, constipation, and feculent vomiting. The operation occupied fifty minutes. A beginning putrid peritonitis was found. In the small intestine was a rupture about three-quarters of an inch in diameter. The opening was closed by means of six Lembert sutures, the abdominal cavity irrigated with a 1 per cent. solution of salicylic acid, a drainage-tube introduced, and an appropriate dressing applied. The operation was followed by threatening collapse, but reaction set in. The subsequent course of the case was favorable, and the man was dismissed at the end of seven weeks. The second case was that of a woman, twenty-eight years old, who, after having received a blow upon the abdomen, presented pain, nausea, bilious vomiting, retention of urine, and tympanites. The operation occupied ninety minutes. When the abdomen was opened, about three pints of brownish fluid of an inoffensive odor was found in the peritoneal cavity, together with evidences of a fibrinous peritonitis. About three feet from the ileo-cecal valve a rupture about two-fifths an inch in diameter was found in the ileum. The opening was closed by means of ten Lembert sutures, the peritoneal cavity was irrigated with a 1 per cent. solution of salicylic acid, and a graduated suture introduced; no provision was made for drainage. In the course of two months the patient was dismissed in blooming health.

The Utility of Tuberculin in Experimental Tuberculosis of the Eye in Rabbits.—At a meeting of the Society of Physicians of the Charité, DÖNITZ (*Deutsche medicin. Wochenschr.*, No. 47, 1891, p. 1289) reported a series of observations in which, by injections of tuberculin, he had succeeded in saving the eyes of rabbits previously inoculated with tuberculous matter. In the animals thus treated the tuberculous process pursued a more rapidly progressive course than in the untreated animals, but ultimately a point was reached when the process becomes regressive, and if the treatment was continued, in the course of three or four months complete functional recovery finally ensued. His investigations lead Dönitz to conclude that tuberculin is a reliable remedy for experimental tuberculosis of the eye of the rabbit. The activity of this agent becomes evident only after tubercles can be microscopically demonstrated. The first effect of the action of tuberculin is a transient but severe irritation of the eye. With the continued action of tuberculin the irritation of the eye subsides. If profound destructive lesions have not preceded the institution of treatment, the functional efficiency of the eye is restored; otherwise atrophy results. To effect a cure it is necessary that tuberculin be given in progressively increasing doses, and that a persistent and not too slight reaction be maintained.

Antipyrin in the Diarrhea of Children.—ST. PHILIPPE (*Journ. Méd. de Bordeaux*) recommends half-grain doses of antipyrin every two hours for diarrhea in children from one to six months old, grain-doses for children up to one year old, and grain-and-a-half doses for children up to three years old.—*Deutsche medicin. Wochenschr.*, No. 44, 1891.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 2, 1892.

PRACTICAL RESULTS OF CHARITY-ABUSE.

THE MEDICAL NEWS of November 22, 1890, contained an article in which the endeavor was made to point out the wrong of indiscriminate charity on the part of hospitals and dispensaries, and to forewarn the profession that the practice was liable to bring about a disastrous revulsion of feeling on the part of the kind-hearted benefactors whose gifts made these institutions and their workings possible. It was argued that the profession owed its younger members some justice and protection; that, putting a premium on pauperism, the custom was often a curse to the recipient; that the charitable public had supposed that it was giving to the needy and not to those able to pay for medical service, and that consequently when the knowledge of the deception should, as it must, finally become well known, deserving charities would be suddenly and savagely checked, and that that medical education dependent upon abundant clinical material would be harmed by withheld subscriptions.

The word of warning fell upon deaf ears. The abuse of medical charity has progressed until, in the rivalry of hospitals for patients, it has become simply ludicrous.

Mark, now, the beginning of the end: The public "Hospital Sunday" subscriptions to the London hospitals this year fell short of the amount given last year by the tremendous sum of $330,000—a fact not to be explained by "hard times," etc., but indubitably explained by the sensible conclusion of sensible men, that there is quite enough real want in the world crying for relief, without encouragement of sham and lying on the part of those able to pay for medical attendance. Those that feel moved to pity by the diseases and suffering of the poor are very liable to have even that praiseworthy sentiment frozen by the thought that their charity is trebly prostituted: 1. To relieve the undeserving that are capable of self-help; 2, by just so much deducted from the due of the needy deserving; and, 3, by the fact that the younger, struggling members of a noble profession are denied their proper *clientèle* by a vicious, unnecessary, and debauching system of encouraged pauperism.

Fast upon the mistaken teachings of many centuries is coming the widespread recognition of the very certain truth, that indiscriminate charity is always indiscriminate wrong. It is a progressive curse, doubling the evil it would halve. But organized and discriminate charity may be made as powerful an agent of good.

Every visiting or resident hospital or dispensary physician that treats patients (except, of course, in emergency cases) without first having made sure by questioning or by some systematic investigation that the patient is needy or deserving, thereby deceives those that originally gave the hospital funds; he puts a premium on pauperism; he encourages a cowardly sort of socialism; he deprives by so much the worthy and needy of their intended and proper care; and, lastly, he degrades the profession to which he belongs.

RESPONSIBILITY AND INSANITY.

SOME time since, in one of our large Eastern cities of the United States, a public officer stole from the people a million or two of dollars. Three well-known physicians of the city were at once quoted in the newspapers in lengthy paragraphs, the essence of their testimony being that the scoundrel was the victim of insidious and progressive cerebral disease, and therefore, of course, irresponsible; the insane asylum, not the prison, was his proper home. This exhibition was a particularly flagrant and outrageous specimen of what is going on about us all the time. Even supposing the contention true (though in

this case it was not true), and supposing that all criminality and crankism are the product of abnormalism of cerebral structure, the publication of the fact in the daily newspaper is wrong: 1, Because such publication brings the medical profession into disrepute—proof of which is patent, but an instance is to follow—and, 2, Because it is wrong for physicians to deliver professional opinions through the agency of the reportorial mind.

The most popular of our American after-dinner orators, in a public speech last week, used these words: "As we have evoluted the theory [of insanity], it threatens to empty our prisons. The old-fashioned way was to lock up people who endangered life or property, or did deeds of violence, for a statutory period; but the new idea sends them to an asylum, to come out in a few months, to the glory of the professional gentlemen who have wrought a wonderful cure, and the terror of the community which is the victim of these experiments."

Now, it is easy to say of this, that it has no more value than the usual post-prandial wit born of champagne bubbles; but a moment's serious reflection will show that this is to shirk responsibility, and hedge the margin of an ugly precipice with rose-bushes. It is idle conceit and partisan bias to neglect the signs of popular mirth mingled with disgust *in re* "the insanity dodge." Doubtless, the bull-in-the-china-shop wrath of Lord Demos has hung and imprisoned many a poor devil that should have had medical treatment instead of punishment. But nowadays there is little danger of that extreme, and very much danger of another the reverse of that. It is brave and often necessary to defy wrong public opinion, but to insult it is something worse than useless, and is apt to be followed by a boomerang effect.

With great travail, scientific medicine is valiantly pawing to get its hinder parts free from the noose of a belated medievalism and the slime of quackery. With slow and labored progress she has risen above the amused contempt of society and literature, and is attaining a position of the highest dignity and honor. There are few ways of undoing this more effective than to encourage lay scorn by an exaggeration of the pathological aspect of criminality. To smudge over or wipe out the delimiting lines of ethical laws, to deny the value, older than the Decalogue and more unerring than instinct, of responsibility, to define sin as disease—all this, were it true, would be impolitic at present. But it has also the excellent misfortune of being in the main untrue, and the shrewd, subtle wisdom of common sense will wink and sneer at the expert testimony vitiated by such unscientific and sorry prejudice.

PALPITATION OF THE HEART.

THE term palpitation is sometimes broadly applied to designate increased force or frequency or perverted rhythm of the action of the heart. It were preferable, however, to restrict the application of the term to the designation of the *subjective* sensation of deranged cardiac action, independently of the character or the cause of the derangement. The action of the heart, as determined by physical examination, may be gravely disturbed, and yet the patient not have the slightest intimation of any abnormality. Here the use of the term palpitation would be manifestly inappropriate. Under ordinary conditions, in health, the individual is totally unconscious of the pulsation of the heart. There may be increased frequency of action both in health (during digestion) and in disease (in febrile conditions), and the patient still be unaware of such pulsation. This surely would not be called palpitation. On the other hand, the individual, under certain conditions, may be alarmed by his sensations when, on auscultation, one is unable to detect any abnormality of cardiac action. This would constitute the simplest type of palpitation. It cannot be denied, however, that in many cases in which abnormal sensations are referred to the heart the action of the organ is deranged. The point that we wish to make is, that palpitation essentially consists in the *sensation*, and not in the physical phenomenon, which is but incidental.

The significance of palpitation, employing the term in the limited sense indicated, is a widely variable one. Of itself the manifestation affords but little aid in prognosis; it is of no diagnostic significance whatever, except it be by directing attention to the heart; it gives no indication for treatment that is not more unequivocally given by other symptoms. The smallest number of those that complain of palpitation have disease of the heart; the largest number are dyspeptics; while the intensity of suffering that may be induced in a hypochondriac is sufficient to give rise to a condition of pseudo-angina. In these, of course, the most brilliant results are to be obtained by careful attention to the secretions, to the digestion, to the

food, and to the mode of life. Even in cases of organic disease of the heart, a distressing symptom may be relieved by the removal of mechanical conditions dependent upon abdominal distention and gastric dilatation, or of irritating influences acting upon the peripheral terminations of the pneumogastric nerve. Among other common causes of palpitation of the heart, other than organic disease, are the excessive use of tobacco, of tea, of coffee, of alcohol, of certain drugs, hunger, loss of sleep, fatigue, exhaustion, sexual excesses, hysteria, and great muscular effort. The manifestation disappears with the removal of its cause.

THE INDIVIDUALITY OF DISEASE.

From text-books and didactic lectures the medical student learns the typical and characteristic symptoms of various affections, and comes to imagine that every disease has clearly-bounded limitations and easily-defined features. It seems to him easy to classify all pathologic conditions, and it also seems that given cases must by their own gravitation settle into distinct groups, and each become recognizable as this or that specific disease. But active practice soon dissipates all such agreeable anticipations. Despite systematizations and cataloguings and scientific generalizations, essential biologic facts refuse such harnessings. There are none of these facts that more intimately come under the spontaneous play of living forces than those of disease; and, if conscientious, the young practitioner soon finds himself at odds with his teachings and preconceptions. Actual diseases do not submit to being jammed into definite classes. There are few or no typical, uncomplicated cases of disease. Complications and possible complications blur all outlines, and every case becomes an individual study, that must be weighed with a quick intelligence, and met with answering adaptations to ever-varying and ever-variant abnormalism of function. Thus the keen mind learns to unlearn rules and systematic classifications, and seeks to gain a subtle intuition and vivid insight into vital conditions and morbid processes. An experienced physician will reach conclusions by means of a hundred little observations and "short cuts" that he will find impossible to explain or to teach to another. Some men have a positive genius of insight into living pathological processes. Nothing, indeed, can take the place of first-hand intelligence. Clinical work, not text-book or quizzing drill, must be the test of medical capacity. There can be no question that in medical colleges there has been an over-emphasis of the value of didactic instruction, and that greater attention must henceforth be given to practical bed-side work. It is a wretched shame that thousands of young physicians have been sent forth to their life-work without personal experience in the recognition and treatment of the many forms of inter-blended, masked, and complicated diseases that are present in almost every sick person.

THE RATIONAL SIGNS OF DISEASE.

To those phenomena that are the direct results of derangement of function may be restricted the designation "rational signs"—in contradistinction to the physical signs, which are developed as the result of conditions purely physical. The distinction is a vital one and of the greatest importance to the clinician. The rational signs represent the functional, the physical signs the structural, results of disease.

In a general way the physical signs make the pathological diagnosis; the rational signs the clinical diagnosis. The rational signs also afford important indications in treatment, and thus aid in the therapeutic diagnosis. The existence of a valvular lesion of the heart, as determined by physical examination, of itself by no means indicates the institution of treatment. This last must be decided by the evidences of disturbance of the functional equilibrium (in the case of the heart described as ruptured compensation): the palpitation, the dyspnea, the dropsy, the weakness, the coldness—in a word, the rational signs.

Under certain circumstances the establishment of the diagnosis essentially depends upon the rational signs. Disease of the muscular structure of the heart may give rise to no obvious physical signs; a deep-seated abscess of the liver may not be accessible to palpation and percussion; so-called central pneumonia may elude the most careful and the most expert physical exploration; and the same may be said of diaphragmatic pleurisy. Most diagnoses by exclusion are based upon the rational signs, which thus may be said to represent an empirical mode of diagnosis.

REVIEWS.

A Text-book of Physiology. By M. Foster, M.A., M.D., LL.D., F.R.S., Professor of Physiology in the University of Cambridge, and Fellow of Trinity College, Cambridge. Fourth American, from the Fifth English edition, thoroughly revised, with notes, additions, and two hundred and eighty-two illustrations. Philadelphia: Lea Brothers & Co., 1891.

Foster's Text-book of Physiology is so well known that a new edition needs but little comment, except to call attention to its excellences and to commend it to all readers; for practitioners of medicine as well as students of physiology will here obtain in a readable form an admirable account of the present state of physiological science. When the merits of this work are considered it is not at all remarkable that it should have passed through four editions and that a fifth should be called for in the space of twelve years. With each successive edition the author has not only incorporated a large number of new and apparently well-established facts, but he has rewritten many of the paragraphs, so that the work represents the present status of many physiological problems. Should anyone desire to obtain an accurate knowledge of physiological processes, as well as to be informed as to the direction in which modern investigation is tending, no better work can be studied than this of Professor Foster. It is unencumbered with details of experiments, with descriptions of elaborate forms of apparatus, with extensive tables of unimportant facts—all of which, however valuable and instructive to the investigator in physiological science, are unnecessary to a clear presentation of the essential ideas for the general student of medicine. All phases of each vital process are stated in a concise and definite manner, and when one rises from a study of these various chapters it is with the conviction that physiology is a real, living science closely related to all problems of clinical medicine.

This fourth American edition contains, as did the previous editions, some gross anatomical facts which, as stated in the preface, are intended to adapt it to the needs of the American student. It is doubtful, however, if the student who is ignorant of these facts is in a proper mental condition to appreciate Professor Foster's expositions; to the advanced student and practitioner they are unnecessary. All the histological features required for an intellectual comprehension of any process were added by the author himself. The work is also profusely illustrated. The publishers deserve the thanks of the profession for a reprint of this valuable book.

Fifth Annual Report of the State Board of Health and Vital Statistics of the Commonwealth of Pennsylvania. Transmitted to the Governor December 2, 1889. 8vo., pp. 734. Harrisburg: Edwin K. Myers, State Printer, 1891.

The fifth annual report of the State Board of Health of Pennsylvania for the year 1889 is a volume of over 700 pages, well printed on good paper, and is altogether a creditable specimen of book-making. It contains a great deal of matter of special interest to the student of public health and hygiene, and at the same time much that has little value outside the official circle represented by the Board. But as it is a record of the transactions of the Board required to be made to the Governor of the Commonwealth, allowance may be made for a somewhat wearisome detail of its proceedings.

As might be expected, there is a very unequal value attaching to the various reports and papers. If possible to select such documents as have a special bearing upon important questions of public health—such, for example, as data relating to etiology of diseases of the infective class, the relation of the pollution of drinking-water to outbreaks of disease, the effects of good sanitary administration, or the reverse, upon the health of towns, etc.—to the exclusion of the description of nuisances of a minor character, it would improve the quality of the volume and enhance its value. This suggestion is not made in any spirit of fault-finding, but in the interest of the busy reader who is dismayed by the difficulties of even scanning the limitless and voluminous publications of the present day.

The scope of the work of the Board during the year may be learned by the perusal of Dr. Lee's admirable prefatory report. This, with the minutes, constitutes the first part. The second part is taken up with appendices embracing reports of committees and of inspection, annual reports of cities and towns, reports of conferences, of the flood at Johnstown and other districts, and quarantine, epidemics, and special sources of disease. The remaining appendices contain a report of the State Pharmaceutical Examining Board, meteorological observations, and other less important items.

Interest in the great catastrophe that befell Johnstown and other districts of the State is revived by the graphic description of the results of that unprecedented visitation of flood. Among the many lessons taught by that experience is the value of an organization like the State Board of Health, which by energy, promptness, and administrative ability, distinguished itself in a marked degree.

It is impossible to attempt more than the briefest reference to this report in the limited space allotted. It is sufficient to say that it contains valuable matter, carefully compiled and systematically arranged, which classes it as a volume that will compare favorably with the best of our State Board of Health reports.

Scientific Medicine in its Relation to Homeopathy. By Professor Theodor Bakody, M.D., of the Buda-Pesth University. Translated from the German by Rudolph F. Bauer, M.D. Philadelphia: Boericke & Tafel, 1891.

This essay, it is stated, was written in response to an invitation from the *Pester Lloyd*, asking for an expression of opinion from the standpoint of the author, concerning the value of the Koch method of treatment, and the similarity of the same to the Hahnemannian methods. With the blind devotion of an idolater, Dr. Bakody acknowledges that "as a scientific follower of the doctrines of Hahnemann," he has "always endeavored . . . . to give the same a suitable, substantial basis, ... in accordance with the scientific knowledge of the day." He builds his superstructure first, and then endeavors to mount it

on a shifting foundation. That he is not an ordinary homeopath, however, is indicated by the fact that he admits of various methods for the treatment of disease, with which, he states, the scientific, educated physician must be familiar. Contrasting what of Hahnemannism he accepts with what he rejects, absolutely or by modification together with what he adds, there is little left on which to base a distinctive dactrine.

Koch's method of treatment is considered "an exact scientific confirmation in vindication of isopathy. The latter . . . . is a branch deviating from the more advanced Hahnemannian principles, and extends far beyond the limits of the law of similarity. . . . . Koch is to be regarded as the scientific founder of the isopathic doctrine." As a result we have homeo-therapeutics and iso-therapeutics. The presumption of the writer of the essay reaches a climax when he says that "Koch's method . . . . is rooted in homeopathic soil; his effort is essentially one in accordance with the Hahnemannian principle."

The aim of tbe true physician is to save life. It matters not to him whether the remedies he employs are designated symptomatic, specific, homeo-therapeutic, iso-therapeutic, antidotal, or what not. He must only not be restrained in their employment by considerations of theory or dogma.

The moral of all the agitation on the subject of homeopathy is that either there is a good deal of deception being practised upon a credulous public, or that the clouds of superstition have not yet been raised.

PRACTICAL INTESTINAL SURGERY. By FRED. B. ROBINSON, B.S., M.D., Professor of Anatomy and Clinical Surgery, Toledo Medical College, Toledo, Ohio. Vol. I, 1891. (The Physician's Leisure Library.) 12mo., pp. 167. Geo. S. Davis, Detroit, Mich.

To those who have followed closely in the wake of the later developments of the great movement in intestinal surgery that was initiated by Senn, at the Ninth International Medical Congress at Washington, in 1887, the name of Dr. Robinson must be familiar. While the author has not entered the literary arena until quite recently, the rapidity with which his communications have followed one another and the energy he has displayed in his experimental work—now represented by over 175 experiments on animals—as well as by his useful additions to the technique of intestinal operations, entitle him to a prominent seat in the bench occupied by the leading followers of the distinguished Western master, to whom this little treatise has been gracefully dedicated.

Outside of the preliminary anatomical sketches of the intestines and peritoneum, which are delineated in an unusually graphic and even picturesque and interesting style, the remainder of the 167 pages that make up the text are devoted to bowel-obstruction in its various phases and to the general and special operative measures that the most advanced surgery has suggested for its relief. Notwithstanding the limitation of his very narrow space, it is remarkable how well the author has succeeded in elucidating the most important technical problems that are involved in the subject. As an ardent partisan of anastomosis and as the parent of the "rawhide" and "segmented rubber plates," it is natural that he should exhibit special solicitude for his offspring in the numerous applications that can be made of these "aids" in anastomosis. To his credit be it said, that in the opinion of one who has carefully tried and compared almost all the numerous "aids" that have been suggested in the last two years as substitutes for the decalcified bone plate of Senn—from Abbe's catgut ring to the latest, Dawbarn's potato plate—none has been found superior to Robinson's segmented rubber plate; none, except the elegant decalcified bone plate at present manufactured under Senn's directions, by Shorse, of Milwaukee.

In addition to the technical innovations described by the author, this booklet contains many facts of a statistical character which are highly creditable to the author's condensing powers; the practical analytical table in the chapter on diagnosis (p. 44) being alone worth five times the price of the volume.

We can only regret, however, that so meritorious a production should have been clad in so poor a raiment; that ideas of merit should have been disfigured by so many glaring solecisms, and particularly by the total disregard of the most ordinary typographical precautions.

A SHORT MANUAL OF ANALYTICAL CHEMISTRY; QUALITATIVE AND QUANTITATIVE; INORGANIC AND ORGANIC. By JOHN MUTER, M.A., Ph.D., F.R.S.E., etc. First American from the Fourth English edition. Edited by CLAUDE C. HAMILTON, M.D., Ph.G., etc. Philadelphia: P. Blakiston, Son & Co., 1891.

THE American edition of Muter's Analytical Chemistry comes to us adapted to the United States Pharmacopœia, with several additions by the American editor. These are made principally in the chapter on the analysis of urine, the tests for certain organic compounds not contained in the English edition, also to the analysis of water, of milk, etc. As a systematic and brief guide for general chemical analysis this work is certainly useful and reliable, one that is well known and adopted abroad. To make such a work, however, a guide for the study of chemistry and chemical analysis by medical students and physicians is a difficult task, notwithstanding Dr. Hamilton's endeavor in this direction. The food-analysis is insufficient, and the chapter on milk, while unnecessarily complicated, must yield results, especially so far as the fat is concerned, that are far from accurate. Under the head of "Wine, Beer, Tincture, or Colored or Sweetened Spirit," an estimation of alcohol contained in these appears to be all that is aimed at, while tests for fuchsin, amylic alcohol, lead, phosphates, sugar, tannin, etc., are not given in connection with them. The analysis of the urine as given here is probably the weakest part of the book. In stating that mucin is also precipitated by the boiling-test for albumin the author is at variance with observers generally. It is universally conceded that if urine is slightly acidulated with acetic acid, mucin, if present in solution, will be precipitated and should then be filtered off before boiling, while the latter process cannot then precipitate mucin. The plates of the microscopic appearance of urinary sediments are the old-time cuts reproduced in an inferior manner. The direct application of Pettenkofer's test, as quoted here, will hardly ever yield any results. The produc-

tion of Teichmann's crystals as a test for blood is not mentioned, nor are pus and acetone as pathological ingredients of urine considered, or tests for them given.

We only select the foregoing points to indicate in which direction the author might have improved his work, and while we do not wish to underrate the value of its strictly chemical part we cannot indorse this work as one of special merit or service as a guide for the medical student or the physician in his chemical work.

A TREATISE ON PRACTICAL ANATOMY FOR STUDENTS OF ANATOMY AND SURGERY. By HENRY C. BOENNING, M.D., Lecturer on Anatomy and Surgery in the Philadelphia School of Anatomy; Demonstrator of Anatomy in the Medico-Chirurgical College, etc. 12mo. pp. xvi, 481. Philadelphia: F. A. Davis, 1891.

IN this work the aim of the author has been to arrange the subject so as to make it equally serviceable as a text-book on anatomy and as a dissector.

The book, according to the author's statement in the preface, is not a compilation, but is the result of years of practical work and a large experience in teaching. The descriptions in the text have been taken from the bone itself and from the subject on the table, and are so treated as to be adapted to the needs of the student.

Some parts of the work are good, as the sections upon the nervous system and the teeth; but other parts are entirely too superficial, as the section upon the vascular system—a division of such great practical importance to the surgeon—in which the relations of the larger blood-vessels are entirely omitted. The text, for the most part, is clear and forcible, but the matter is less extensive and less complete than any one of the well-known and much-employed compends of Potter, Nancrede, or Young. Its position as a literary effort is between such condensed and complete works as those mentioned, and such practical treatises as those of Heath, Holden, and Weise; and considering the limited character of the work, it would better have been called a hand-book, since it is neither a compend nor a treatise. The print is large, and the illustrations, especially the original cuts, are clear and good. The statement, however, is made in the preface that the illustrations have been carefully selected and their sources credited; on looking carefully through the work, except those few that are known to be original, many of the cuts are recognized as old acquaintances in Wilson and Heath, while others of them are reduced from the first English edition of Gray's *Anatomy*, but in not a single instance is the source credited.

The great fault with the work is its incompleteness—an error of omission rather than of commission—necessitating reference to standard treatises or recognized compends.

For example, the synovial membranes, other than those of the wrist and tarsal articulations, are not mentioned; "the great vessels and nerves, and some muscles," that pass through the superior opening of the thorax are not named. It is remarked that "the breasts are abundantly supplied with blood," and the blood-supply of the organs of special sense, of stomach, intestines, and ovaries, are passed in silence under the description of these viscera.

Less than four lines are devoted to the mediastinum. The orthography is correct, except the confusing description of the corpuscles of *Pacini* as the *Pacchionian* corpuscles (p. 438).

In a word, the incompleteness of the work must necessarily limit its field of usefulness.

SYLLABUS OF THE OBSTETRIC LECTURES IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA. By RICHARD C. NORRIS, A.M., M.D., Demonstrator of Obstetrics, University of Pennsylvania, etc. Second edition. Philadelphia: W. B. Saunders, 1891.

BOOKS of the class to which this one belongs would do little harm if their employment were restricted to the legitimate objects to which such publications are devoted—that is, as a guide or index to higher study. Too often, we fear, however, they are utilized as text-books, with the contents of which the student can become sufficiently familiar to make a good showing at a quiz-demonstration, or to pass a formal examination. By their use the stimulus to intellection is removed, and study becomes perfunctory, the processes by which knowledge is rendered permanent and valuable and fruitful are permitted by inactivity to become degenerate. The student could better afford to cover less ground thoroughly, so as to be familiar with every step of his way, and not be lost in a wilderness of meaningless language. The mind that is led along low levels cannot be expected to rise to great heights.

Such books are necessarily inadequate to the wants of the student. In the hundred or two hundred pages allotted them they can only deal superficially and incompletely with the vast number of subjects that come within their scope. That defects and imperfections of statement should occur will occasion no surprise.

This syllabus—the first edition of which was exhausted in eighteen months, and which is conveniently interleaved for the addition of notes—is not worse than many of its congeners, and is better than some. It is only to be regretted that a demand has been created for books of its class.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK. Eighty-fifth Annual Session, held at Albany, February, 1891. Philadelphia: Wm. J. Dornan.

THE association the volume of Transactions of which is under review comprises some of the foremost physicians of this country; consequently, the contributions contained in the work are, in greater part, of more than ordinary value—representing, as they do, the views of men thoroughly competent to speak authoritatively on the subjects treated. Unfortunately, the space at our command does not admit of a detailed account of all of the articles, or even of many of them that are deserving of an extended notice; therefore we shall be obliged to content ourselves with a brief mention of those papers which, in our opinion, are especially valuable to the general practitioner:

The discussion on "Tuberculosis" includes a paper on "Its History," by Dr. H. R. Hopkins; "Its Pathology and Etiology," by Dr. Heneage Gibbes; "Tuberculous Manifestations in the Upper Air-tract, and Special Treatment Thereof," by Dr. John O. Roe; "The Treatment of Tuberculosis, including Prophylaxis as Related

to Climate," by Dr. Samuel R. Ward; "Its Treatment as Related to Therapeutics," by Dr. E. L. Shurly; "Inoculations with Professor Koch's Tuberculin," by Dr. A. Jacobi; and a paper on "Koch's Treatment in the Mount Sinai and the New York Polyclinic Hospitals, February, 1891," by Dr. Henry Newton Heineman. These papers occupy nearly sixty pages, and taken *en masse* may well be considered to represent the present status of the disease under consideration.

Dr. William Wotkyns Seymour next considers "The Treatment of Gall-stones." This writer is opposed to protracted medical treatment, and advises operative measures when the attacks are of increasing frequency and severity. The operation he recommends is cholecystotomy, the mortality of which procedure, he asserts, is probably less than 5 per cent.

The discussion on "Appendicitis" includes papers by Drs. Charles McBurney, William W. Keen, Lewis A. Stimson, George R. Fowler, Robert F. Weir and A. Vander Veer. Taken collectively, they leave but little to be said on the subject.

The paper on "The Pathology of the Caisson Disease," by Dr. Howard Van Rensselaer, is of exceedingly practical importance, and the author is to be congratulated upon the interesting and scientific manner in which he has presented the results of his investigations. This article was the Merritt H. Cash prize essay of the New York State Medical Society, 1891.

Taken in its entirety, this volume of the Transactions of the Medical Society of the State of New York maintains the high character of the former issues for useful, scientific work.

THE URINE, THE COMMON POISONS, AND THE MILK. MEMORANDA, CHEMICAL AND MICROSCOPICAL, FOR LABORATORY USE. By J. W. HOLLAND, M.D., Professor of Medical Chemistry and Toxicology, Jefferson Medical College of Philadelphia. Illustrated. Fourth edition, revised and enlarged. Philadelphia: P. Blakiston, Son & Co., 1891.

THIS little work ought to be so thoroughly well known as to require no introduction. It contains, conveniently arranged and easy of access, a good deal of information especially adapted to the wants of the student in the pursuit of a practical knowledge of the methods of making clinical examinations of the urine and of the milk and the tests for the more common poisons. The book can conveniently be carried in the pocket, and is peculiarly suited for use in the laboratory. It can confidently be recommended to students and practitioners.

MINISTERING WOMEN: THE STORY OF THE ROYAL NATIONAL PENSION FUND FOR NURSES. By GEORGE W. POTTER, M.D. London: "The Hospital," 1891.

THIS interesting account of the founding and growth of the Royal National Pension Fund for Nurses will find, no doubt, in England a large number of readers. The object for which the author and his friends are working will naturally appeal most warmly to the community in which this work has been carried on. The name of Junius S. Morgan, however, so closely identified with the success of the undertaking, will cause the book to be received with interest in this country.

The writer has endeavored to state the history of the Pension Fund in clear terms, so that the account will appeal, first, to the body of trained nurses, and in the most common-sense way; and, secondly, to the charitable public. It is to be hoped that this book will attract the attention of the nurse-schools in this country, to the end of awakening a general interest in a similar undertaking, and of arousing nurses as a class to the importance of provision for their future condition.

CHILDBED NURSING. By CHARLES JEWETT, A.M., M.D. New York: E. R. Felton, 1891.

THIS manual contains in forty pages all that is of practical value to nurses and graduates upon the subject of obstetrical nursing. The author has adopted an arrangement in which the essential points are included in condensed paragraphs under general headings. The reader is thus enabled to take in at a glance the teachings of the lecture-course and ward-training, arranged in a classified form.

Some of the directions are somewhat absolute, and the writer asserts himself with unusual positiveness in regard to certain points that admit of difference of opinion. This, however, is a consequence of the manner in which the book is compiled, and detracts in no respect from its usefulness as a manual of exact teaching.

THAT UNCOMFORTABLE SHOE. A Treatise written in Clear and Plain Language on the Foot and its Uses in Walking, the Ill-fitting and the Comfortable Shoe, the Causes of and Remedies for Cobblers' Cripples, Corns, Bunions, etc., Containing also a Chapter on the Care of the Feet, and Describing the Taking of a Cast of the Foot. By AVARD J. MOORE. Profusely illustrated. New York: M. T. Richardson, 1891.

THE foregoing is sufficiently descriptive of the scope of the booklet that bears its title. The author, "a practical shoemaker," has admirably succeeded in presenting in a clear and comprehensive manner all that is worth knowing of the foot as an agent in progression, and of the means of providing it with a suitable and properly adapted covering. The book can be read with profit and advantage by both those who make and those who wear shoes.

3000 QUESTIONS ON MEDICAL SUBJECTS, ARRANGED FOR SELF-EXAMINATION, ETC. Philadelphia: P. Blakiston, Son & Co., 1891.

A little vest-pocket booklet, of 144 pages (a blank-leaf alternating with the printed ones), containing test-examination questions upon the different subjects of the medical student's studies, and with numbers following each question that refer to books and pages wherein the answers may be found. The books referred to are for the most part the Blakiston "Quiz Compends."

THE PHYSICIAN'S VISITING LIST FOR 1892. Philadelphia: P. Blakiston, Son & Co.

A PUBLICATION so well known that special commendation is superfluous. The dose-table contains a parallel

column giving the metric equivalent of the apothecaries' weight.

RECORDS OF THE ASSOCIATION OF ACTING ASSISTANT SURGEONS OF THE UNITED STATES ARMY, A.D. 1891. Edited by W. THORNTON PARKER, M.D., Recorder A. A. A. S., Salem, Mass. Salem Press Publishing & Printing Co., 1891.

THIS volume, excellently printed and bound, will be prized by army surgeons for its biographical information. It contains a transcript of United States Army regulations concerning acting assistant surgeons and other pertinent information.

THE MEDICAL NEWS VISITING LIST FOR 1892. Philadelphia: Lea Bros. & Co.

A MOST serviceable helper for the general practitioner, and one of which by experience he has learned the usefulness. The present edition has in many ways been revised and improved.

BURDETT'S (ENGLISH) HOSPITAL ANNUAL AND YEAR-BOOK OF PHILANTHROPY, 1891–1892: Containing a review of the position and requirements of the Voluntary Charities, and an exhaustive record of Hospital Work for the Year. It will also be found to be the most useful and reliable guide to the British and Colonial hospitals, dispensaries, nursing and convalescent institutions and asylums. London: "The Hospital," 1891.

A VALUABLE and trustworthy reference-book, the purpose and scope of which are expressed in the title-page quoted.

NEWS ITEMS.

Muscular Development Late in Life.—The *Lancet* describes a military bicycling trip in which one hundred miles were made in about ten hours. The veteran cyclist, Major Knox Holmes, almost at the close of his eighty-third year, mounted on a tandem, accompanied the corps, and arrived at the termination of the expedition five minutes in advance of the rest. He was a little distressed on dismounting, from too hard riding the last few miles, but he soon threw off his fatigue and joined his companions at dinner with thorough zest. His condition is physiologically peculiar. In twelve weeks' new training he has, in the most striking manner, "developed muscle" in the external and internal vasti, the rectus, and the muscles that form the calf of the leg—in refutation of the physiological doctrine that after threescore years and ten there is no new development of muscle.

The Late Dr. S. R. Knight.—At a recent meeting of present and former members of the medical staff and ex-residents of the Episcopal Hospital the following minute was adopted:

The present and past members of the medical staff of the Episcopal Hospital and its former resident-physicians desire to express the deep regret which the death of Dr. S. R. Knight has caused them. All of the many who have been associated with him in his long service as Superintendent of the Hospital feel that they have lost a sincere and honest friend. They remember the kindly advice, the shrewd help and counsel that he had always ready for their difficulties, professional and personal, his constant interest in all the varied work of the institution, and the wisdom with which he made his own duties at once an example and an opportunity to the younger men in the sphere of their labors.

Eleventh International Medical Congress.—At the recent Italian Congress of Internal Medicine arrangements were inaugurated for the next International Medical Congress, which is to meet in Rome in 1893. The last two weeks in September would be the best time for the meeting. Baccelli has been made chairman of the organizing committee; Maragliano, general secretary. There will be twelve sections represented respectively as follows: Anatomy, Antonelli; physiology, Albini and Albertoni; pathology, Bizzozero and Foà; pharmacology, Cervello; clinical medicine, Baccelli, Maragliano, Murri, and Bozzolo; surgery, Bottini; obstetrics, Morisani; psychiatry, Morselli and Tamborini; ophthalmology, Devincenzi and Secondi; dermo-syphilopathy, Campana and Barduzzi; forensic medicine, Tamapia; hygiene, Pagliani, Celli, and Canalis.

The Association of Military Surgeons of the National Guard of the United States will hold its second annual session at St. Louis, April 19, 20, and 21, 1892. An interesting program of addresses by prominent surgeons of the National Guard and of the United States Army has been arranged, and scientific papers on military and accidental surgery will be discussed. Dr. Eustathius Chancellor is chairman of the Committee of Arrangements.

The Southern California Medical Society held its eighth annual meeting at Riverside, on December 2 and 3, 1891. Norman Bridge, M.D., of Chicago, read a paper "On the Later Methods of Treating Tuberculosis," and William A. Edwards, M.D., late of Philadelphia, in conjunction with James Sears Waterman, M.D., of New York, presented "A Study of Hepatic Abscess, with the Exhibition of Post-mortem Specimens."

The Late Dr. Lippert has bequeathed four thousand five hundred dollars (eighteen thousand marks) to the medical faculty of the University of Berlin for the endowment of a prize.

Fischer, formerly Professor of Psychiatry at Prague, died recently.

CORRECTION.

In the report of a case of amebic dysentery, on page 659 of THE MEDICAL NEWS of December 5, 1891, the figures "eight or ten millimeters" apply to the *circumference*, and not to the diameter, as stated.

CAN WE DRAIN THE FALLOPIAN TUBES?

BY SARAH E. POST, M.D.,
OF NEW YORK CITY.

IN speaking of drainage of the Fallopian tubes, we do not refer to artificial incisions, but to the question as to whether in pathological conditions we can utilize the natural outlet of the Fallopian tubes for drainage.

Theoretically, nothing would seem to be more certain than that we can drain the Fallopian tubes through the uterus; practically, nothing seems less to be expected. I have a certain amount of evidence, but evidence that is of an inferential character, and that perhaps requires corroboration in a more extensive field. I have therefore chosen to present the matter interrogatively. In a quiet way I have been studying this subject for the last six years. Reports of a number of the cases thus studied will be found in medical journals as follows: *N. Y. Medical Record*, January 15, 1887; *N. Y. Medical Journal*, September 24, 1891; *Transactions of the American Gynecological and Obstetrical Association*, 1889; *American Journal of Obstetrics*, February, 1891. From these reports it will be seen that I think that by palpation I can diagnosticate a prolapsed and swollen tube; that I can overcome the adhesions that often imprison the collections in these tubes; and that I have evidence of the discharge of such collections through the uterus.

METHOD OF EXAMINATION.—I cannot make this diagnosis *per vaginam* by the index finger alone. I examine by rectum in virgins, and in married women I use my first two fingers, or insert my whole hand up to the thumb. I use the hand corresponding to the side affected. Where the whole hand is employed, I place the patient upon the back, and the palmar aspect of the fingers reaches the patient's opposite side. It will be seen that the examiner's left hand is applied to the patient's left side, and the right hand to the right side, even in the dorsal position. When one or two fingers are sufficient, I prefer to have the patient upon the side, and I believe that a better conception of the conditions is obtained when the affected side is uppermost. Whether this is true or not, a good deal is gained by examination upon both sides. While examination by rectum gives you a nearer access and enables you sometimes to make out the relations of the uterus better, I think that for an appreciation of the adhesions that bind down the tubes the vaginal examination is the more useful.

CONDITIONS FOUND.—Examination may disclose a swelling in the anterior cul-de-sac, directly continuous with the horn of the uterus; a swelling at the side close to the uterus and displaced with it; or, more frequently than either of the foregoing, an adherent mass posteriorly to the uterus, from which the cervix cannot be separated. Any attempt to withdraw the cervix from this mass gives pain. The posterior cul-de-sac is characteristically short and tense. You may be able to outline the tube in this position, or you may not. The first two delineations represent practically the same condition—a collection of pus, or perhaps the peculiar milky tubal secretion, without adhesions, as a rule; the last, a catarrhal condition, with posterior prolapse, peritonitic inflammation, and adhesions binding the mass down. This condition is at least sometimes secondary to the other two. It seems to follow discharge or absorption of the accumulation, when these occur without the precautions of treatment. Apparently the previously distended tube prolapses from loss of tone, and either before or after prolapse retrostalsis of its secretion establishes the adhesions in which it is imbedded. I have twice had return of the lateral accumulation after liberation of such a posteriorly-adherent tube. While the resulting condition was to myself more alarming than the original one, it was without suffering, and the patient, previously regular in presenting herself for treatment, could no longer be induced to continue her attendance at the clinic. Subsequent examination in one of these cases showed disappearance of the secondary collection, the tubes remaining in place.

HISTORY.—The history of salpingitis is, as a rule, very characteristic. Usually it dates back to a severe illness, with confinement to bed, with fever, and pain, for which quieting medicine was required. In the active stages there are profuseness and irregularity in the menstrual flow. Later, with contraction of the adhesions, scantiness in the flow is not uncommon. Sterility is the rule. Dysmenorrhea is present, I think, in all cases. This dysmenorrhea is peculiar; the pain either precedes or follows the flow. A leucorrheal discharge, not thick and tenacious, and that may even be described as watery, is characteristic of these periods. This discharge may

be readily differentiated by its characteristics and history from the product of cervical or endometrial catarrh. The accumulations at the side and in front of the uterus are comparatively without pain. During the intermenstrual intervals the woman with the pus-sac does her work without discomfort. The suffering in the cases in which the displacement is posterior and bound down by adhesions is, on the contrary, enormous. This suffering is not expressed alone in actual pain, but also in the protean forms of hysteria, of which I am inclined to think it the most efficient cause. The patient has sacral and inguinal pain; also, as a rule, difficulty in walking, is irritable and suffers from headache, dizziness, impairment of vision, and other nervous disorders.

The Question of Drainage.

Chronic catarrhal salpingitis. Here the question of drainage is complicated with that of the liberation of the tube. I think that in a certain number of cases I have overcome the adhesions that bind down these tubes, have restored them to a somewhat normal position, and have drained them through the uterus. My reasons for thinking this depend upon disappearance of the posterior mass, deepening of the cul-de-sac, relief of pain and discomfort, menstrual regularity, demonstration of an unusual discharge in some cases, and, last, pregnancy after sterility of from four to six years. Of the latter I have reported three cases (*Journal of Obstetrics*, February, 1891).

The treatment has extended over a period varying between six months and three years. As a rule, for the first three months, all procedures must be experimental. By this I mean that treatment must be limited to hot injections and the careful application of tampons. My object in treatment from the first is the stretching of the posterior cul-de-sac. Tenderness determines the degree of pressure that can be borne. In some cases applications of iodine seem to reduce the sensitiveness. When cotton tampons are used, iodine at least does no harm. I have seen no special good from the use of glycerin. The patient is told at the commencement of her treatment just about how long it will take to give her relief, and almost without exception her previous sufferings have been such that she acquiesces with patience in the more or less protracted preparatory treatment. Having established a degree of tolerance in the part, I next introduce the inflated-ring pessary. This is the old-fashioned air-ring. It is inflated to almost its full capacity. As sold, these rings are either too tense or too lax. The tension may be regulated by means of the hypodermatic needle and an atomizer bulb. Upon some part of the circumference will be found a mass of wax. It is through this mass that the needle should be plunged. The bulb may be attached after insertion. This is an important matter, as its degree of tension determines the value of the ring.

In application the ring should be large enough, so that the anterior portion is depressed by the pubic bone, the posterior rising and distending the posterior cul-de-sac. First applications may be painful; if this is the case, the ring should be withdrawn within a half-hour or worn only a short time and reintroduced at the end of two or three days. As a rule, when there has been preparatory treatment, tolerance is perfect from the first, and the results obtained by means of the ring are far superior to those of the tampon. Within a few days the cul-de-sac will be deepened, and with this stretching of the cul-de-sac pain will have disappeared. With the ring in position the patient will walk even from the first the usual distances walked by women and will be surprised at her renewed incapacity when the ring is withdrawn. The difficulty of walking is not alone immediate discomfort, but the production of a train of persistent nervous symptoms. The sufferer from chronic salpingitis must keep still, because if she walks she will have a "nervous headache" as a result, or she becomes "irritable," or "her eyes give out," etc. This woman may have an appearance of health and among her friends the difficulty pass as a fancy, the condition contrasting in this respect with the appearance of the patient in ovarian prolapse. Almost without exception the friends will tell you that the person could walk if she would—that she is, in fact, hysterical and the victim of a fancied incapacity. I regard the difficulty of walking as due to imprisonment of the fimbriated extremity of the tube, which, particularly in walking, is thus subjected to friction between the uterus and rectum. The ring by separating the uterus from the rectum relieves the source of friction and supports the sensitive part, often from the first, even before liberation is effected. The fact of a material basis for the woman's incapacity has been repeatedly proved by her immediate resumption of active habits upon the application of this support. For details I refer to several cases reported in the *New York Medical Journal*, September 24, 1887. After a period varying between six months and a year the cul-de-sac may be found empty and the ring can be discontinued. Presumably the liberated tube resumes its normal position. I have in some cases found a subsequent return of the contraction in the floor of the cul-de-sac, without prolapse of the tube, again fixing the uterus and causing renewed pain. In such a case a return to the ring for a month or two will restore the part to a comfortable condition. In still other cases the patient has, after the establishment of apparent cure,

returned with a sharp attack of inflammation, and, in one case, a renewed accumulation, this time at the side of the uterus. In such a case treatment must be the same as for a primary attack. The ring is not applicable in acute conditions; it should be dispensed with and the patient should have rest from active work. Even without such rest, however, I have at the end of three months found the parts in a condition permitting the resumption of the ring, and with it a return of health. I might add that, even in a condition of great sensitiveness —even in a condition of invalidism—the application of this ring will afford a consciousness of capacity for effort, and in a surprisingly short time even the constitutional appearances of health. While, therefore, the system of treatment may appear tedious, and even unduly prolonged, it does not have this character after the first three months. The patient manages her ring herself, and she does not, as a rule, return to the physician until it has to be renewed. While wearing the ring the patient feels and looks well, she becomes unconscious of her malady, and as time elapses forgets to wear the ring at all; she thus accomplishes her own cure; such forgetfulness, in my experience, indicating absence of the conditions for which the ring was applied.

Perhaps I need not explain that it is difficult for me to mention any considerable number of cases that I can follow further. In some, however, absolute cure, so far as replacement is concerned, does not occur. The patient continues to have intervals of renewed symptoms, and she again and again returns to the ring when thus troubled, or when called upon for unusual work. I have, however, other cases in which absolute disappearance of the difficulties traceable to the prolapse has resulted. The patient has had no need to return to the ring, and she even forgets the details of her former sufferings.

The occurrence of a discharge through the uterus in this class of cases has been pretty thoroughly established. It has happened in a number of instances that the patient has herself reported an unusual discharge of a watery character shortly after commencing to wear the ring. I have associated this discharge in my mind with the liberation and elevation of the tube. It has been irritating in some cases, the irritation subsiding, however, after a few days, without local treatment.

The patient inserts this ring herself. She is directed always to leave it out at night. By this means cleanliness is assured, and the muscular tone of the vagina is preserved. I think, too, that the effect upon the broad ligaments themselves is better than if the support were constant. In removing the ring the posterior fourchette should be drawn backward with the finger so as to admit air to the vagina. Otherwise the patient will pull against a vacuum, and downward displacement of the uterus and more or less pain will follow. In inserting the ring the woman assumes the squatting position. She folds it into a boat-shaped mass, and if well lubricated with vaselin it is inserted without difficulty. She then assumes the knee-chest posture, when it rises spontaneously to the desired position.

Pyosalpinx. I would here like to refer to two cases, both, in part, previously reported.

The first is that of a single woman, aged twenty-two years, who presented herself in November, 1888 (*Trans. Amer. Gyn. and Obstet. Soc.*, 1889), with retroflexion, a mass posterior to the uterus, consisting apparently of an adherent ovary and tube, and at the left side a tumor the size of a walnut, representing apparently a tubal collection. With elevation of the uterus this tumor became softer, and diminished in size. Since the report referred to, the girl has married. She tells me that some time ago her husband contracted a mild type of urethritis that his physician ascribed to his wife's leucorrheal discharge. The woman herself remains practically well—that is, she looks and feels well. She has still a retroflexion, an adherent mass upon her right side, and a pus-sac upon her left. She returns about once in six months with increased size in the tumor, and a return of discomfort. She is tamponed for about a week or longer, and the discomfort disappears while the sac contracts.

The second case (*Amer. Journ. of Obstet.*, Feb., 1891) may be briefly described as a case of sterility, with a cachexia resembling that of chronic tuberculous abscess. The patient was first seen in June, 1888. Examination showed the uterus fixed, and two globular masses also fixed in the pelvis, one posteriorly and to the right, and one on the left side. In June, 1889, the tumors are said to be smaller, less tense, and the uterus more movable. The patient somewhat later discontinued treatment. In September, 1890, she returned with a four months' pregnancy, the uterus being drawn to the right side by the adherent mass. Sugar and albumin were present in the urine shortly before term. The patient was delivered February, 1891. The labor was without complications, but the child had for some days been dead, and the placenta was degenerated, so that it was bloodless, it was said. Convalescence was prompt, and there had been no return of the accumulations, while the cachectic appearance, previously so marked, had been almost lost.

I regard these two cases as cases of undoubted pyosalpinx on account of the persistent refilling of the sac and the urethritis in the first case, and on account of the cachexia in the second. From the history, too, I see no reason to doubt that we have here had drainage through the uterus. In both cases the inflated ring was worn for a period of from six to twelve months. In both cases the present health of the patient is good.

A third case may be added:

This patient came to me in June, 1888. She was a woman of fifty-five years, who had reached the menopause seven years previously. The patient complained of distress on walking, and nocturnal pruritus that often awakened her from sleep. She was not conscious of any discharge. Examination showed a zone of irritable appearance in the neighborhood of the carunculæ myrtiformes. The vagina above was pale and the cervix atrophied. There was retroflexion of the body, which seemed membranous and soft, and yet globular. The examination suggested to me a cystic growth, yet the sound entered to the fundus, and the cavity measured two inches. The examination produced no discomfort. The patient told me that she had at some previous time suffered from a pelvic abscess that discharged through the rectum, but I did not connect this fact with the condition before me. The body could be replaced, and with the patient in the lateral position I inserted a tampon, using two pledgets of cotton, one posteriorly to the body, and one below and in front to keep the first in place.

The patient walked with comfort, went about to a number of stores, and did some shopping that afternoon. She returned in the morning, however, with her napkin and clothing saturated with a watery, vile-smelling discharge, leaving a brownish tinge. This discharge had evidently become established during the night. It persisted for a day or two, when the woman left town (she lived in a neighboring city). I have learned from her physician that she subsequently suffered from a return of her "pelvic abscess," and that the discharge was through the rectum as before. This physician had not had her attention directed to the uterus as a possible means of drainage in this case. The inference seems to me, however, quite justifiable in view of the amount and offensiveness of the vaginal discharge following the use of my tampon.

Follicular salpingitis. I have one case that seems to me to come under this heading:

The patient was a woman, then forty-two years old, who came to me in 1885 with a retroverted uterus and both ovaries prolapsed. Menstruation was profuse, lasting a week. The condition had been of long standing, and the patient suffered from pronounced melancholia and hysterical attacks, with convulsive seizures lasting for hours. (This case is referred to as Case II, *N. Y. Medical Record*, January 15, 1887.) At the date of that report the hysteria had been overcome, and the prolapsed ovaries and uterus would retain a normal position for some days at a time without support. A laceration of the cervix was operated upon December 31, 1887. The patient suffered from hysterical mania after the operation and recovered slowly.

The patient presented herself again May 20, 1888, with pain radiating from the sacral region. I have a very vivid impression in regard to the pain in this case. It was acute and unbearable, contrasting with her former ovarian pain,[1] and keeping her awake at night. The recumbent position gave no ease. Examination at this period showed a mass in the posterior cul-de-sac the size of a hazel-nut and very sensitive. The uterus was in position; the cervix was united and healthy; the ovaries were large, but high and movable.

On May 25th the patient returned relieved of her pain, and saying that she had had a cheesy discharge that could have been scooped from the vagina with a spoon. Examination showed no irritation of the vagina, while the tumor could no longer be found in the cul-de-sac. A series of these enlargements followed. May 30th, a tumor the size of a hazel-nut was found in the left tube a half-inch from the uterus. Several nodules were found also in the right tube. The affection lasted for over a year, with intervals of comfort. The height of distention would always be characterized by great pain, after which the cheesy discharge, and relief followed. On March 13, 1889, I have an entry showing the uterus to be healthy, menstruation lasting but three days, the uterus not fixed, no accumulations, and the parametria not sensitive, although the cheesy discharge at intervals recurred. At the last date mentioned, March 13, 1889, the patient suffered from pain in the chest, and examination showed a questionable condition of the lungs. The signs were obscure. During the year the patient had lost flesh. At the present time the discharge has apparently ceased, the accumulations no longer form, but we have, progressing apparently, a tightening of the broad ligaments, so that the uterus is becoming fixed.

In this case I do not think that there has at any time been a peritonitis, and for this reason it seems to me probable that the shortening of the ligaments is due to cicatricial contraction of the ruptured follicles. The uterus is now in retroversion, but the ovaries are high; and unless doing very hard work, or trying to walk a long distance, the woman feels comparatively well. She has regained a good weight, and looks well. She sleeps, being no longer disturbed, as during the most of her previous menstrual life, by pain. She is able to do her housework, including her washing. It seems probable that with the establishment of the menopause the cicatricial tissue will support the retroverted uterus so as to give her complete comfort. A pessary or tampon of any description cannot now be worn.

Follicular salpingitis has been described by Martin. I have no particular example with which to compare my case, but the history seems to me to point to this disease.

The treatment has been limited to the use of the

[1] I might add that the nervousness of salpingitis also contrasts markedly with the depression and melancholia characteristic of ovarian cases. In my experience the ovarian cast of countenance is never assumed in salpingitis. If at ease and spared exertion, the patient suffering from salpingitis is cheerful and looks well.

hot douche, and, during the earlier stages, support. With the progress of cicatrization, as I have explained, support has ceased to be borne.

The question of discharge through the uterus does not, I think, admit of doubt in this case.

LITHEMIA.[1]

BY A. STEWART LOBINGIER, M.D.,
PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF COLORADO; PATHOLOGIST TO THE ARAPAHOE COUNTY HOSPITAL; PATHOLOGIST TO THE DENVER WOMAN'S HOSPITAL, ETC.

THERE are many questionable theories concerning the production and elimination of uric acid. It will not be the purpose of this paper to expose their fallacy or to discuss at great length the merits of the more rational views. It will be sufficient to consider some of the well-defined clinical facts that have been forced upon the notice of the writer by the frequency with which he has encountered the condition designated lithemia.

Murchison was the first authority to clearly define and discuss that morbid condition of the blood due to functional derangement of the liver, and characterized by an excess of uric acid in the urine.

It was formerly an accepted theory that a nitrogenous diet must be strictly prohibited in the treatment of lithemic subjects. Although by certain of our British confrères this view is still maintained, there is among physicians that have devoted especial study to the subject a growing conviction that the very converse of the old theory is more nearly correct, and that the impaired metabolic power of the liver is generally due to an excessive fatty and carbohydrate diet.

The *causes* of lithemia may be briefly summarized as follows:

1. Improper food, producing acid indigestion.
2. Indulgence in beer, wine, and spirituous liquors.
3. Lack of proper air and exercise.
4. Various nervous influences.
5. Inherited dyscrasiæ.

Finally, any influence that tends to diminish the alkalescence of the blood, or that overworks the hepatic cells and arrests the complete oxidation of proteid material, may be sufficient to cause the presence of uric acid in excess or of oxalate of calcium in the urine. The mere presence of uric acid, *per se*, is no evidence that this substance is being produced in excess. It is simply thrown out of solution by a relative diminution of the alkaline bases with which the uric acid is combined. The condition must be caused by a chronic impairment of digestion before it can be strictly classed as pathological.

[1] Read before the Colorado State Medical Society, Denver, June 17, 1891.

I believe that no cause operates so constantly in producing a lithemic condition as excessive indulgence in sugars, starches, and fats. Such a diet sooner or later is apt to be followed by acid indigestion, with languor, flatulence, and constipation. In the majority of cases there will be either rheumatic or neuralgic pains, especially if there are very large deposits of uric acid and oxalate of lime. The conversion of farinaceous substances into glycogen and the emulsifying of fats is at once arrested; fermentation results, and lactic, butyric, and other abnormal acids are formed. The absorption of these acids brings about a pathological condition of the blood characterized by diminished alkalescence. This change in the blood has probably an irrritating effect on the liver and brain that tends to prolong and aggravate the lithemic state.

It has been suggested by Draper that there exists a close relation between the functional disturbance of the liver in lithemia and in glycosuria. The marked nervous disturbances attendant upon lithemia would clearly indicate that the cerebro-spinal system was subjected to considerable irritation. But whether irritation of the floor of the fourth ventricle has any influence in the production of uric acid or not is a question belonging to the realm of speculation.

The habitual ingestion of beer and wine has always been recognized as a potent cause of lithemia and oxaluria. Fermented liquors are absorbed and carried to the liver in almost their full strength. When brought in contact with the hepatic cells the alcohol acts as an irritant, congestion and functional impairment result, and metabolism is retarded. Besides the deleterious influence of alcohol on the liver, wines and beers contain acids. These acids when absorbed tend directly to reduce the alkalinity of the blood and to the precipitation of uric acid. Again, copious ingestion of spirituous liquors will in time impair the digestive power, and the acid indigestion produced is a third and potent influence in the production of lithemia.

Murchison is at great pains to enumerate the admissible and inadmissible liquors, but concludes it were better to prohibit all spirituous drinks. As a compromise he would allow claret and dilute spirit. My experience has been that the allowance of any kind of liquor, however mild, is followed by relapse, and disappointment to both patient and physician. Many cases continue incorrigible because liquors are clandestinely taken and it is impossible to enforce prohibitive measures. Were any proof needed to support a generally accepted belief, the results obtained in these cases, when it is possible to secure abstinence, would be sufficiently convincing.

The following cases may illustrate the effect of alcoholic liquors both in causing and aggravating lithemia:

CASE I.—L. H., sixty years of age. When I was called to see the patient he was in a paroxysm of pain presumably due to the passage of concretions along the line of the ureters. After relieving the pain an analysis of the urine was made. It was found high-colored and intensely acid, containing large quantities of rosette crystals of uric acid. Inquiry revealed the fact that for fifteen years of his life the patient had been in the habit of taking a cocktail before breakfast, on the presumption that digestion was thereby improved. There was a history of muscular rheumatism, especially lumbago, and of periods of mental depression or nervous irritability. After putting the patient upon a diet largely nitrogenous in character and obtaining his promise to abstain from all kinds of malt and spirituous liquors, a few aids to digestion proved sufficient to entirely correct the lithemic condition.

CASE II.—J. C., twenty-eight years of age, complained of acid indigestion, languor, flatulence, and muscular rheumatism. As commonly happens in such cases, he insisted that "his kidneys were out of order" and "had fears of incipient Bright's disease." His diet was mixed and so were his drinks. He found beer, ale, whiskey, and wine equally potable, so long as the source was copious. He never went on sprees, and assured me that he was quite temperate, rarely taking more than eight or ten glasses of beer, with a glass of wine or whiskey, during the twenty-four hours. Analysis of the urine showed great quantities of calcium oxalate, uric acid and débris, with some pus-cells, leucocytes, and epithelium from vesical irritation. The patient was induced to live a more quiet, regular, and temperate life; the necessary restrictions in diet were recommended, and digestive ferments and antiseptics were exhibited to promote complete conversion of the food. The result was a speedy abolition of the symptoms of lithemia and a return to health and comfort. But the patient, from time to time, proved intolerant of restriction, and every indulgence was followed by a relapse; so that he was ultimately dismissed.

CASE III was a gentleman sent to Colorado for pulmonary hemorrhage. On consulting a physician here, he was advised to drink all the whiskey and beer his constitution would bear. After some months the patient began to develop symptoms of lithemia. Not realizing that liquors were aggravating his trouble, he continued their use for over a year, when his discomfort obliged him to seek relief.

He was advised to abstain from all stimulants. This task was no easy matter for one accustomed to copious daily stimulation. He soon became entirely free from the lumbago, lassitude, and mental depression that had made him so wretched. From time to time, however, thinking himself entirely recovered, he would relax his care in respect of drinking, and would at once have a return of oxaluria and its attendant symptoms. Later on, when for social reasons he was induced to indulge his taste even lightly for an evening, he would come to me complaining bitterly of the penalty he had to pay.

It is but fair to say that it is not common to meet with cases as sensitive to alcohol as the one last cited; yet the difference between this case and the others mentioned is only one of degree.

In male subjects, as we have seen, lithemia is often traceable to indulgence in spirituous liquors; but when this condition occurs in middle-aged and elderly women it is generally due to sedentary habits and mal-nutrition. The lack of fresh air and exercise is attended with lowered oxidation, constipation, and hepatic engorgement, thus affording favorable conditions for the formation of uric acid. No class of cases is more difficult to treat than these. The working-cells of the liver must be fed by pure blood in order to maintain their activity and fulfil their function of converting proteid material. Fresh air is required to supply pure oxygen to the vitiated blood, and exercise is necessary to send that blood briskly coursing through the portal system. Frequently the physician's ingenuity is taxed to the utmost to secure implicit obedience in regard to diet and habits of life.

The influence of nervous strain has much to do with the arrest of the normal gastric and hepatic functions. I have met with many cases in which mental anxiety was clearly responsible for chronic mal-nutrition and lowered oxidation. It is true that among such cases acid fermentation from improper diet is frequently met with; but clinical evidence is abundant in support of the view that nervous irritability is more frequently the cause of lithemia than its concomitant. It may safely be predicted that the many puzzling phenomena seen in functional disease of the liver will never be elucidated until we have a clear comprehension of the innervation of that organ and its central connection.

Inherited dyscrasia has long been recognized as an influence predisposing to lithemia and gout. It is questionable just how much derangement may be ascribed to inherited functional deficiency; but many cases present themselves for treatment in which a rheumatic, gouty, or lithemic diathesis has been apparent along the line of hereditary descent.

The question of *prognosis* in milder cases of lithemia scarcely calls for serious consideration.

If a few precautions in regard to diet, exercise, and open-air life are closely observed, the functional difficulty will correct itself. But the history of the average lithemic patient is one of oft-repeated relapses from periods of improvement. To secure happy and permanent results requires long and persistent adherence to principles of regimen and treatment. Muscular and articular rheumatism, nervous irritability, insomnia, and mild melancholia, the sequelæ of lithemia, make it a disease of no trifling significance. A few resist all ordinary means of treat-

ment, and in such cases we must exert constant vigilance to arrest the onward progress toward gout or calculus. No pronounced precipitation of uric acid or oxalate of calcium can occur for an indefinite time without setting up catarrhal inflammation in the renal pelvis or bladder. When once this catarrh becomes excessive, vesical calculus will result from decomposition of the urine and phosphatic incrustations.

Briefly stated, the *treatment* of lithemia consists in the removal of its causes, affording the liver an opportunity to accomplish its metabolic function unimpeded; but the successful management of this disease involves strict adherence to detail.

Attention to diet is of paramount importance. Discriminating care is necessary in the choice of food easy of digestion and least liable to fermentative decomposition. Starches, fats, and sugars stand first on the list of foods to be avoided. Potatoes, corn, rice, radishes, cabbage, and fibrous vegetables are inadmissible in the average case of lithemia. In severe cases fruits, and even bread, may have to be limited. Highly acid fruits, such as strawberries, blackberries, oranges, and occasionally apples, are arrested in digestion, and the liver is irritated by the products of decomposition.

Fat, in the form of lard or oil, proves exceptionally pernicious; even butter must be limited in quantity. It should be emphasized that no food for the lithemic subject should be fried or prepared by the aid of any fat.

All sweets, whether in the form of sugars, syrup, candies, or pastries, are especially liable to early fermentation. Sugars in excess overload the hepatic cells and impair the glycogenic power of the liver, arresting the complete conversion of nitrogenous products. It is not at all uncommon for a patient suffering from lithemia to appear asking treatment for acid dyspepsia, pyrosis, flatulence, and lumbago, with the statement that "all he has been able to eat with any zest is pancakes and maple syrup." Would it be possible, in the whole category of dietetics, to select a combination of substances more potent in the production of fermentation and dyspepsia?

It should be understood that the foods mentioned in the foregoing list may be considered allowable only upon careful consideration of the case in hand. No empirical statement can be laid down that will apply *in toto* to every case.

Among the foods that may be allowed the lithemic subject are eggs, broiled meats, fish, oysters, game, and tender fresh vegetables. Milk, cocoa, and abundance of pure water should be taken as drinks; but at no time should any amount of liquid be taken with solid food at meals. Few influences operate more harmfully in the production of acid dyspepsia than the common habit of drinking freely at meals. The gastric juice is thus diluted and rendered powerless to attack the solid ingesta. The free use of water an hour before or two hours after meals contributes greatly to the relief of a torpid liver, and flushes out the kidneys in a simple but effective way not accomplished by any other means.

It is important that the quantity as well as the quality of food should receive attention. The gastric and hepatic functions are often impaired by over-feeding, when a smaller amount of ingesta would be easily appropriated.

Finally, it will be necessary to prohibit every form of alcoholic stimulants. I have never known a case of lithemia that did not suffer immediate relapse on the return to alcoholic drinks, even in small quantities. No exception can be made to the rule of exclusion, unless it might be light claret or gin, and both of these liquors have so often deceived me that I have lost confidence in the authority that has allowed even this concession.

Next to care in diet, systematic outdoor exercise and open-air recreation figure in importance in the permanent cure of lithemia. Several months in the woods or at the seashore often prove most effective in obstinate cases. No exercise should be engaged in so violently as to rob the centers of oxidation of their required amount of blood. Exercise carried to exhaustion is more harmful than a sedentary life.

In most cases of lithemia it will be found necessary to employ some aid to digestion to insure the complete conversion of food.

The administration of nux vomica, bismuth, and soda before meals, and pure pepsin with dilute nitro-hydrochloric acid after meals, will, in the majority of cases, prove sufficient. Nitro-hydrochloric acid may do more harm than good when exhibited in cases in which there is an excessive amount of native acid in the stomach, or where for any reason it passes rapidly into the circulation, thereby reducing the alkalescence of the blood. As an oxidizing agent experience shows it has no superior, and it is supposed to have a special action on the liver.

Alkalies are often administered to correct a lithemic condition, but their excessive use is erroneous. The continued administration of alkaline salts usually lowers the gastric tone to such a degree as to set up the very conditions that induce lithemia.

Sodium phosphate proves a valuable saline in cases in which the liver is primarily at fault.

Chloride of ammonium acts happily when there is continued engorgement of the portal circulation.

Salicylate of sodium has been highly spoken of by certain German authorities, but its unhappy influence on a stomach already weakened by irritants makes it a doubtful drug in lithemia.

Perhaps no medicinal agents act more satisfactorily in stimulating the liver than the various saline

waters, such as those of Vichy, Ems, Buffalo Lithia, and our own Manitou. In the majority of instances the chief benefit derived is from the thorough washing out of the débris of oxidation from the system. The chemical influence is largely of secondary importance.

Experiments have shown that in many cases equally good results have been obtained from drinking copiously of simple water. All mineral waters act best when taken warm, and while fasting. In chronic lithemic subjects, when the formation of stone in the bladder is to be apprehended, the continued use of selected mineral waters as a prophylactic is excellent practice.

A CASE OF PRIMARY LUPUS OF THE PHARYNX.

BY JONATHAN WRIGHT, M.D.,
OF BROOKLYN, N. Y.

THE recent flurry among the miracle-seeking members of our profession, caused by Koch's premature announcement, has been at least productive of the publication of records of cases of lupus.

For a number of years it was thought that lupus of the mucous membrane of the nose and mouth was always an extension, by continuity or contiguity, of a similar growth on the skin. In the last seven or eight years, however, reports of carefully studied cases have made it probable that a very large proportion (from 20 to 45 per cent.) of all cases of facial lupus really begin in the contiguous mucous membranes.[1] The painless character of the growth is an explanation of this former oversight on the part of clinical observers. Fifteen years ago, Von Ziemssen[2] rightly prophesied, and the prophecy was echoed by Lefferts,[3] that a more careful search would reveal many cases of lupus of the throat. Lennox Browne[4] has lately said that in a skin hospital he saw in a few weeks more cases of lupus of the nose and throat than he had previously seen in a throat-practice of twenty years. For a number of years nearly all the standard works and monographs have referred to the case mentioned by Von Ziemssen in 1876 as the only one reported in which the disease was primary and confined to the larynx. This statement is certainly erroneous, since Haslund,[5] in 1883, reported a case of lupus confined to the larynx, while Obertüschen[6] recorded a case in which the lupus first appeared in the larynx of an otherwise perfectly healthy individual; a year and a half later skin-lupus appeared on the nose, the laryngeal lesion having healed. Others more or less doubtful have been reported. Primary lupus of the tongue, though almost as rare as that of the larynx, has been observed by Fairlie Clarke[1] and Leloir.[2] Primary lupus of the soft palate and pharynx is more common, while the nasal mucous membrane is very frequently the starting-place of facial lupus. Of course, many of these cases are open to justifiable doubt in regard to the diagnosis; but in the light of the more recent publications of clinical experience one should hardly be satisfied with the declaration of Lefferts (*loc. cit.*), Störk,[3] and others, that they would decline to make a diagnosis of lupus of the throat without coëxisting skin-lupus. Such isolated disease, as stated above, is by no means rare, Chiari and Riehl,[4] as long ago as 1883, having reported thirty-eight cases of lupus of the larynx. Many more have been reported since.

The following case of primary lupus of the pharynx is, however, the only one that has ever come under my observation. It must be remembered that lupus is one of the diseases that is, judging from literature, much more common in Europe than in this country.

F. F., male, seventeen years of age, an iron-worker, of German parentage, came to the Demilt Dispensary in May, 1890, because his mother, on looking into his throat, had discovered its abnormal appearance. There was no record of hereditary tuberculosis, cancer, or syphilis. The patient himself gave no direct or indirect history of acquired syphilis. About six months previously he began to notice that his throat was dry, his nose was stopped, he breathed through his mouth, and a tickling in his throat made him cough a little. He was slightly deaf on the left side. Three or four months ago he had some lumps removed from the left side of his neck. It was impossible to ascertain whether the appearance of the lumps followed or preceded the throat symptoms, which were exceedingly slight, there being no dysphagia and but little discomfort.

The boy's appetite and general health were good. His appearance was robust; with the exception of the scar at the angle of the jaw on the left side, where enlarged glands could still be indefinitely felt, he presented no external evidence of tuberculous disease. There was no skin-lupus. A physical examination of the chest revealed nothing abnormal. The fauces were seen to be thickened and covered with numerous tiny, shining elevations of the surface. There was some congestion, but no ulceration. The thickening was more marked on the left side. The uvula was enormously hypertrophied, being nearly as large as the distal phalanx of the middle finger. It also was sprinkled with little surface elevations, and near the tip this appearance was exaggerated to such a degree as to be called fungous.

[4] Vierteljahresschrift für Derm. und Syph., 9, 182, p. 661.

There was some reddening around the edges of the infiltrated area on the soft palate, but the tubercles themselves were pale and shining. There was very little secretion. There was some linear cicatricial tissue on the posterior pharyngeal wall. There was no pain on swallowing, or on manipulation. The patient complained only of a clogged feeling in the throat. There was some hypertrophy of the nasal mucous membrane, and some deviation of the septum to the left. It was thought that on the right side a few shining points could be seen on the inferior turbinated bone far back, but at that time this was not satisfactorily established.

After exclusion of syphilis by a thorough but fruitless course of potassium iodide and mercury, the diagnosis of lupus was made. With the cold snare the whole uvula was amputated as close to the velum as possible. Vigorous applications of pure lactic acid were made. The infiltration seemed to subside somewhat, and the patient being relieved of the symptoms that annoyed him, ceased to attend.

A microscopic examination of the excised uvula proved conclusively that we had to deal with a tuberculous growth, notwithstanding that it was impossible to demonstrate the presence of the tubercle-bacillus in the ten or fifteen sections stained for it.

Gottstein,[1] in his excellent work, gives a good description of the microscopic appearances in a case of lupus of the uvula, and a reference to his account will give an almost exact picture of my case. Sections were submitted independently to several experienced microscopists, who all agreed as to their tuberculous nature. Several laryngologists saw the case, and the diagnosis of lupus was undisputed.[2]

On the arrival in New York of Koch's fluid—tuberculin—the patient was hunted up and induced to place himself under treatment. Before the inoculations I find in my history-book the following note:

"At the base of the amputated uvula on the anterior inferior edge of the soft palate, there is a rosette of small pin-head, pale, shining tubercles. Here and there a few may be seen along the arch of the soft palate and on the anterior pillar on the left side. The latter is fast to the tonsil, which is hypertrophied. On the posterior pillar on the right side there is a suspicious-looking spot. The epiglottis is thickened, but it is impossible to determine the presence of the little tubercles seen elsewhere; otherwise the larynx is normal in appearance. The patient having had some nose-bleed from the left side, careful examination reveals a little patch of tiny tubercles about the middle of the convex surface of both the middle and inferior turbinated bones on that side. No true ulceration and no destruction of tissue, no breaking down of the epithelium, can be discovered anywhere in the nose or throat."

The patient at that time (December 23d) was shown at the laryngological section of the Academy of Medicine. On December 24, 1890, the patient received his first inoculation with 0.001 of tuberculin, followed at the usual intervals by two or three others. The reaction was characteristic, the fever reaching 101° F., with malaise, etc. The little tubercles that before had been pale-red and shining became white at their centers and looked as if they would soon break down. This, of course, made them much more noticeable, but I am unable to say whether, as Virchow has claimed, new ones were formed, or whether the previously-existing but unnoticeable ones were accentuated and made more evident. There was, of course, a great increase in the congestion; the reddened areola was very marked, and the patient complained of his throat being sore.

He had evidently satisfied himself concerning the effect of the tuberculin and escaped from the hospital. All subsequent attempts to induce him to return were of no avail. In the light of our present experience the folly of his conduct will not appear so glaring as it then did.

The differential diagnosis of syphilis, lupus, and tuberculosis of the mucous membranes—"the three grand processes," as some Frenchman calls them—often presents insurmountable difficulties, even to the most trained and experienced observer, yet typical cases of each are unhesitatingly recognized by the clinician, so unmistakable are their characteristics. The majority of writers claim that there are more cases on the diagnostic border-line between syphilis and lupus than on that between tuberculosis and lupus. I have seen one case of syphilis in which, on the aryteno-epiglottic fold, there was an appearance almost identical with that described in the case here reported—the same absence of ulceration, the same shining, tiny tubercles. Other manifestations, however, and the result of treatment proved the specific nature of the case.

Clinically, tuberculosis of the throat is a painful, ulcerating, non-cicatrizing affection, almost always combined with visceral tuberculosis, and accompanied by signs of systemic enfeeblement and marked decline of the general health. Lupus, on the contrary, is comparatively painless, does not always tend to the formation of true ulcers, and as it advances leaves cicatricial tissue behind it. As a rule, the general health is not affected. It is a matter of dispute whether there is any great preponderance of visceral tuberculosis among its victims, though the weight of evidence, at least in a slight degree, affirms the fact. In considering this question, however, it is always well to remember that about one-third of *all* autopsies show the presence of active or latent tuberculosis, or the evidence of

[1] Krankheiten des Kehlkopfes, 3d ed., p. 277.

[2] I have also in my possession sections of several specimens of syphilitic disease of the uvula and soft palate, and the contrast between the two forms of inflammation in this locality is striking and interesting.

previous tuberculosis. Moreover, although lupus may be followed by tuberculosis in one-half of the instances, it has never been shown that lupus is any more liable to attack the skin or mucous membranes of a consumptive than to attack those of a healthy person.

The writer does not wish to insist on the non-identity of lupus and tuberculosis. He wishes, however, to insist on the Scotch verdict—"not proven." Clinically, we all know the difference in the pictures summoned to the mind of the laryngologist by the words "lupus" and "tuberculosis." The order of frequency of the occurrence of tuberculosis in the air-passages—and it is of this locality only that the writer pretends to speak—is lungs, larynx, pharynx, nose; while of lupus, it is nose, pharynx, larynx—and lungs never (?).

Histologically, we know how trifling is the difference. The greater vascularity and the fewer areas of coagulation-necrosis, the fewer giant-cells in lupus, are merely matters of degree. The difference in the number of bacilli found in the two processes is, however, too striking not to be significant. In Dr. Rice's recent admirable article[1] on lupus of the throat, there is one point that arrests the attention of any one conversant with the subject, and that is the finding of a considerable number of bacilli in the secretions from the lupus-patch on the face. Through his courtesy I had the privilege of seeing his case, in which the throat lesion differed from that in my case only in the stage of the process and in the location.

The difficulty of demonstrating the tubercle-bacilli in the lupus-tissue is great, it being necessary, usually, to stain many sections before even one bacillus can be made sure of. While I have made no *exhaustive* search for the fact, I have been unable to find in very extensive references *any* record of the bacillus tuberculosis having been found in the secretions of true lupus.[2] L. V. Krynski,[3] however, described a case of facial lupus in the discharges of which he could, as usual, find no tubercle-bacilli; after the first injection of tuberculin, none; after the second, two; after the third injection, countless numbers. After later injections, none were found, except after the fifth, when two were noted. Dr. Rice's paper does not record the relation of the bacterial examination to the time of inoculation.

In the early days of bacteriology the new school had its strongest claim to the belief and confidence of the medical world in the irrefutability of the evidence it presented. Presumptive evidence was ruled out with scorn. We are now asked to accept the tubercle-bacillus as the chief, if not the sole factor in the etiology of lupus. No one has ever produced, no one has ever claimed to be able to produce lupus by inoculation of the tubercle-bacillus. Tuberculosis is frequently, but not constantly, produced by the inoculation of lupus material; lupus itself has never been reproduced by inoculation. Thus we see that the bacteriological evidence of the identity of the etiology of the two processes is far from satisfactory. We can only suspect that lupus is a variation of tuberculosis. If it should ever be *proved* to be, the term lupus must still be used to indicate a distinct clinical condition.

To ask the observer of diseases of the throat to believe that the two processes are identical in their etiology, is to ask him to lay aside the use of his reason and to disregard the evidence of his senses. He may, however, be disposed to admit the probability of the identity of certain factors in the etiology of each, for disease is not a plant, nor is it an abnormal agglomeration of cells in a certain constant order of arrangement; it is "a derangement of any of the vital functions" (Webster). Pathological changes are the results of disease, not the disease itself.

It is perfectly within the range of possibilities, and it is daily becoming more probable, that the same microörganism may cause more diseases than one. It is perfectly certain that we hardly have a disease known to man that is due to any one cause. It is natural for man to seek a simplicity of relation between cause and effect. Such simplicity does not exist between the manifestations, the lesions, and the etiology of disease. Classification of disease is the means, not the end, of its study; and at present no classification is possible that is satisfactory, and it is futile for medical men to try to drag certain clinical manifestations of disease into line with the minute pathological changes with which they are associated. Systems and rules are the crutches with which the medical novice learns to walk, but the sooner he throws them aside when he is on his feet, the less he is encumbered.

PHARYNGO-MYCOSIS.[1]

BY HENRY BIXBY HEMENWAY, A.M., M.D.,
OF EVANSTON, ILL.

PHARYNGO-MYCOSIS is often a very annoying trouble for the general practitioner, by whom it is generally confused with other troubles, especially with follicular pharyngitis. The mild nature of the disorder does not compel a close examination, and even specialists are frequently ignorant of its nature.

[1] Abstract of paper read before the Chicago Medical Society, December 7, 1891.

There is reason, however, for believing that it is far more common than is generally believed. Most cases are treated by general practitioners.

There are many forms of pharyngo-mycosis. That due to the growth of the oïdium albicans (which has been more recently identified with the mycoderma vini and saccharomyces albicans) has long been known, and generally resides in the mouth. Nigrities linguæ resides especially on the tongue, and it is probable that when sarcinæ are found in the pharynx they are the secondary result of a like growth in the stomach. Other cases of mycosis in the pharynx have been ascribed to the growth of aspergillus fumigatus, actinomyces, leptothrix buccalis, and bacillus fasciculatus. It is more especially to the last two forms mentioned that this article applies.

But few references are found in literature to the subject. A careful search failed to discover more than four articles in American medical journals. Most articles upon the subject have appeared in the French and German journals. England has added almost nothing to our knowledge, and most textbooks are silent upon the subject. This is especially remarkable when we remember that the first article on the subject was published in 1873, and that the affection is extremely difficult of treatment, except by surgical means.

The etiology of pharyngo-mycosis is very uncertain. Catarrhal inflammation is a predisposing cause. Mouth-breathing brings the air in direct contact with the tonsils, and favors the implantation of the microphyte. Hypertrophied tonsils favor its development. Damp, unhealthy surroundings are predisposing causes. It is more common in females than in males. It has been found in the vicinity of diphtheria. The form of the bacillus suggests that it is perhaps closely related to forms found in stagnant water. Lennox Browne mentions unhealthy skin as a cause. Dental caries is also mentioned as a cause, favoring the development of leptothrix.

Pharyngo-mycosis is essentially a chronic affection, subject to exacerbations and abatements when left to itself. The subjective symptoms vary from a very slight tickling sensation to a decided feeling of obstruction. Sometimes nothing is felt. At other times the local irritation produces a local inflammation, accompanied by the usual symptoms of tonsillitis or pharyngitis, such as pain and fever. The irritation of the fungus frequently causes a hacking cough, sometimes accompanied with vomiting. The voice is sometimes altered. If constitutional symptoms are present they are secondary. Asthma is sometimes present.

Objectively we see spots upon the pharyngeal wall or around the circumvallate papillæ of the tongue that vary in color from white to cream or yellow. When circumscribed upon the tonsils they are seen to grow from the crypts. They are very tenacious, not easily broken off, and when removed they are rapidly reproduced in the same locality, sometimes within twenty-four hours. The growth is generally in the form of filaments or tufts; sometimes it is confluent in the form of a membrane. Normally the mucous membrane around the fungus is natural in color.

Mycosis is differentiated from diphtheria by its chronic nature; by less tendency for the fungus to spread; by absence of fever and symptoms of systemic disturbance (except when accompanied by tonsillitis); by absence of the diphtheritic odor; by absence of pain, and by the form of the fungus. When in the membranoid form, it does not come off as a membrane, but breaks in pieces. When removed it sometimes leaves bleeding-spots, but the mucous membrane is not so much denuded as in diphtheria.

In follicular pharyngitis the contents of the follicles are easily expressed. The calcareous concretions sometimes found in chronic follicular amygdalitis often project from the crypts, but they are also easily expressed. Though in follicular inflammations the accumulations frequently *contain* leptothrix threads, they are not *composed* of the filaments.

The filaments of pharyngo-mycosis are easily seen, often without staining, with an amplification of 600 diameters. They are brought clearly to view with an aqueous solution of methyl-blue. Anilin-red, or an aqueous solution of potasium iodide and iodine, also stain well. In the specimens examined by the writer, the filaments were arranged in bundles or fascicles, which sometimes branched, though the filaments themselves did not branch. In other cases the filaments were not in bundles, though lying parallel; sometimes they were arranged in the form of a network. The filaments are generally found more or less intermixed with fine granular matter, which is frequently arranged in lines from which the bacilli generally project at an obtuse angle. The filaments or bacilli are normally straight, or nearly so, though they may be found flexed almost into the form of an ellipse.

The writer was unable to find a description of Sadebeck's bacillus fasciculatus, but since he found the bacillus so frequently in fascicles he regarded his specimens as of that species. He frequently found the leptothrix filaments, but the constant form was not leptothrix. Leptothrix buccalis filaments are from 0.7 to 1 μ broad, and the cells measured by the writer were seldom over 3 μ long. The bacillus of mycosis, however, varied in thickness from 0.4 to 0.56 μ, generally about 5 μ long, but sometimes 16 μ in length. The bacilli do not show a tendency

to form long threads, as seen in the leptothrix. There are reasons for suspecting that the bacilli have some power of locomotion.

A large majority of observers have seemed to agree that leptothrix is the cause of pharyngo-mycosis. So far, however, as found by the writer, their descriptions are not those of leptothrix. Leptothrix is common, especially upon the gums; but mycosis is rare, and not found on the gums. It would be strange if leptothrix were not frequently found with mycosis, but its presence does not prove that the growth is the result of leptothrix.

Prognosis. The affection is generally more troublesome than dangerous. The fungus is slowly destructive of the tissues on which it grows. It may be implanted on the Schneiderian membrane or lodged in the lungs. In the latter location it might prove serious. Spontaneous cures sometimes occur. In other cases the disease is extremely chronic. No treatment is satisfactory except the use of the galvano-cautery. With few exceptions, and those doubtful, drugs have been absolutely useless. The bacilli penetrate deeply into the tissues, and the treatment must be correspondingly energetic. Since they seem to thrive best in an acid medium, the writer recommends the application of the negative electrode, with a large external positive electrode.

This paper is based upon a case that the writer observed for five months, and which had been called one of follicular pharyngitis. Antiseptics, caustics and pepsin were all unable to destroy the microphyte. Nothing was heard from the patient after the removal of the growth by the galvano-cautery.

THE AMEBA COLI.

BY JOHN H. RHEIN, M D.,
OF PHILADELPHIA.

As the relation between the ameba coli and dysentery is yet a matter of doubt, the following observations may be added to the accumulating testimony on the subject.

The question grows more complex when it is considered that the ameba has been found in the stools of children with catarrhal diarrhea, in the urine of phthisical patients, and in the pus of abscesses of the liver; while in a recent epidemic of dysentery in the Norristown Insane Asylum, careful examination of the stools failed to find in any case the ameba coli.

The theories as to the nature of this organism that make it an intestinal epithelial cell or an especially well-nourished leucocyte have thus far scarcely been maintained.

In a series of fifteen cases of dysentery that have come under my observation amid the same climatic and hygienic conditions, the ameba was readily found in the stools of all. The examinations were made with the aid of one-twelfth oil-immersion and one-fifth lenses.

The organisms varied in size from two to several times that of the white blood-corpuscles, and contained one or more vacuoles and some amorphous granular matter. Their outline was faint and indistinct, so that at first the organism was not easily distinguished.

When at rest the organisms appeared circular, or nearly so, unless they had died in the act of protruding a pseudopod, an event of not infrequent occurrence.

The vacuole varied in size. In some amebæ it was found to be small, in others so large as to occupy the greater part of the organism. (Fig. II, *b.*)

There was no constancy in the amount of granular matter, as indicated in the accompanying illustrations. When small in quantity it was found aggregated at the periphery of the ameba; if the amount was large, it occupied the entire organism, together with the vacuole. The motion was relatively slow or rapid, and included a slow, irregular movement of the whole ameba, a wave-like movement of the contour, and a dancing of the granular matter.

Fig. I represents the changes in two amebæ that took place in the course of a few minutes, the stool having been examined an hour after its evacuation. It is to be noticed that the granular matter changed position with each wave-like motion, the wave beginning at one side of the body and ending at the other in the extrusion of a pseudopod, each movement occupying about three-quarters of a second. These were rhythmically repeated a number of times. (Fig. I, B.)

The movements, when slow, seemed to be associated with an entire change in the shape of the organism, and in two cases there appeared to be a cycle of motion. The original shape being circular, or nearly so, there followed a variety of forms, so that finally the original shape was resumed. (Fig. I, A.)

The change in position occasioned by the currents in the fluid of the specimen examined must not be mistaken (as it may easily be) for this movement.

The motion seen in the granular matter was very rapid, and consisted of a dancing of the small particles, which soon established a current around the vacuole, so that the granules were carried around in the current, making repeated excursions. In one instance, though the observation was continued for a long time, no change in the contour of the ameba was discovered.

The pseudopods resembled small corpuscles attached to the ameba, and when, as is often the

case, the granular matter extends to the base of a pseudopod, there is an appearance of two distinct bodies. (Fig. II, *a*.) The pseudopods varied in number, there being usually only one or two, but, as was once seen, there were five. (Fig. II, *c*.)

Fig. I

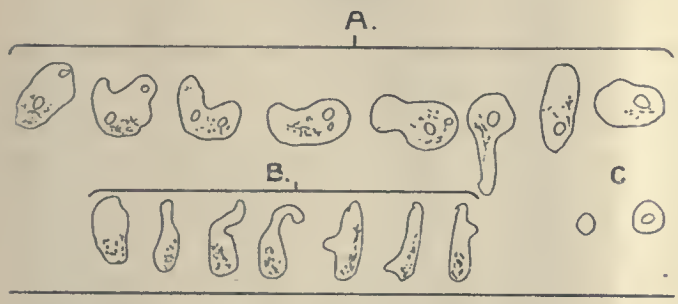

Fig. II.

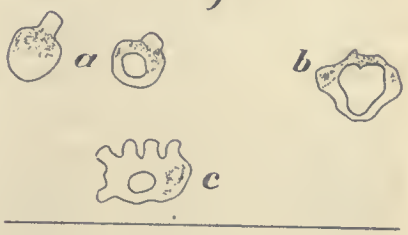

In a few cases the ameba appeared to be motionless, though every precaution was taken to preserve life, and the observations were carefully made. There was some difficulty in preserving the vitality of the ameba sufficiently long to observe its movements, and it became necessary to use means to keep the stools at the body-heat, to use warmed slides and cover-glasses, or a warm stage. Even when these precautions were taken the organisms continued to live only for from ten minutes to two hours.

An attempt was made to stimulate the amebæ to movement after they had apparently died, and in one case five pseudopods were protruded, while in others some slight motion was occasioned, but the results were by no means constant. In two cases the cercomonas intestinalis was discovered in very active motion.

ORIGINAL LECTURE.

CHOREA IN PREGNANCY—PUERPERAL INSANITY—THE CARE OF THE UMBILICAL CORD—MAMMARY BINDERS—RECTO-VULVAR FISTULA—MAMMARY ACTIVITY AND MENSTRUATION IN THE NEWBORN—LUMBO-SACRAL KYPHOSIS, ETC. ETC.

BY BARTON COOKE HIRST, M.D.,
OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL, AND PROFESSOR OF OBSTETRICS IN THE UNIVERSITY OF PENNSYLVANIA.

CHOREA IN PREGNANCY.

OUR first patient has, to a slight degree, the chorea of pregnancy. You observe the twitching of the right shoulder, of the head, and of the neck, as she sits before you. I question her about her condition, and her embarrassment, you see, increases; she squirms about on her chair, so that the choreic movements are somewhat masked, but you may still perceive them. The case is one of mild chorea in pregnancy. Even in this form it is a rare disease of pregnancy—I have seen but three cases.

In reply to my question, the woman tells me that for two years past she has had St. Vitus's dance, but not to such a degree as at present; that she had a bad attack of rheumatism three years ago, and that she knows nothing of her family history. These three points are always of interest in the study of the chorea of pregnancy. Heredity, preëxisting chorea, usually in childhood, and rheumatism are the three main etiological factors. The two other cases that I have seen were very much more marked than this. In both I was obliged to interrupt pregnancy late in its course. It should be remembered that there are two grades of chorea in pregnancy: one a mild, the other a severe and malignant disease in which the mortality is over 30 per cent. The mild cases, however, may grow progressively worse, and become malignant, so that whenever chorea occurs in pregnancy the woman must be carefully watched, in order that gestation may be interrupted in time, if the movements become so violent as to threaten exhaustion. In my first case of chorea in pregnancy, I managed to control the disease and even to diminish it until the last weeks of pregnancy, when, in spite of treatment, the movements became rapidly more constant and violent, and I induced labor. In the first few days of the puerperal state the chorea disappeared. This case had a very interesting history. As a child the girl had had chorea, but had been cured by competent medical attendance at that time. Three or four days after the illicit intercourse that resulted in impregnation the chorea reappeared. The other case that I have seen was in a girl who was at the same time insane, the chorea, however, by a few months antedating the insanity. She, too, had been illegitimately impregnated, but was afterward married to the father of her child, who then deserted her. This girl came of a neurotic family. She developed a type of insanity that I shall exhibit to you later in to-day's lecture. In her case I also interrupted pregnancy, not entirely on account of the chorea, but partly because she had a high grade of generally-contracted pelvis, and pyelitis also, so that, taking everything into consideration, I thought she would be better off if the pregnancy were terminated as soon as the viability of the child could be pretty well assured. Consequently, I induced labor about five weeks before term. The child did well, and the mother made a complete recovery. I accomplished a cure in her case;

I believe, by improving the condition of her blood. As in a large number of insanities in the childbearing woman, I found in her a very marked anemia. Under the prolonged use of iron and arsenic I increased the number of red blood-corpuscles from less than 3,000,000 to more than 5,000,000 in the cubic millimeter, and as the blood approached the normal the girl rather suddenly recovered her reason, the chorea having disappeared long before. This is the best medicinal treatment of which I know—the combined administration of iron and arsenic for the chorea of pregnancy. It cured one case, it held another case in check until the latter part of the pregnancy, and we learn the same lesson from the history of cases in the hands of other physicians. We shall, therefore, try it in the case now before us, and shall with interest watch its effects. This, I think, is the only treatment we shall have to employ. I do not believe that in the next two months the disease will assume so serious a nature as to demand interruption of pregnancy. The patient will, however, be carefully watched. I have, myself, never seen the truly malignant type of chorea in the pregnant woman, although one of my cases nearly approached it. Dr. Goodell, however, as you may perhaps remember, has seen a remarkable instance of this sort, and in his inimitable manner has described it. The woman in labor jerked and contorted her limbs and body with such violence that she spattered the walls of the room with her blood as high as a man's head, although she was delivered on a mattress upon the floor. She afterward died of exhaustion. That was a typical case of malignant chorea—a condition that, whenever possible, must be guarded against by the timely interruption of pregnancy.

PUERPERAL INSANITY.

The next patient has puerperal insanity—in connection with the study of chorea an interesting condition, because the two are sometimes associated. This woman is married, about thirty-seven years of age, has had four children, the last about a month ago. After the birth of the child before the last she was irritable, and at one time violent. Her family did not think her insane, however, and she remained at home, and after some weeks she recovered her normal state of mind. During the last three weeks her husband has had no work, and has pawned the household goods, one article after another, to obtain money for drink. The woman left her bed at the ordinary time and busied herself with her housework, according to the statements of her family manifesting no unusual mental symptoms, except "fits of temper," until a few days ago, when she began to have delusions and became violent. When she first entered the hospital it was not easy to detect the mental disorder, although the next day her insanity was very apparent. She started for the window, saying she wanted to go home, and was just prevented from jumping out. As you can see from her appearance, the woman's physical condition is bad. Her breasts furnish little nourishment for the child, which must therefore be fed artificially. As I now ask the patient a number of questions about herself and her family, you hear that her answers are clear and rational. It takes a close and continued observation of this woman to show her true condition. The only thing abnormal I notice now is the slowness with which she appears to understand my questions. There is a mental apathy or lethargy that, in a more pronounced degree, I have often seen in the insanities of the childbearing woman. There is in these cases a complete indifference to surrounding conditions and events. The lethargy is profound. One is reminded of the poetical picture of the lotus-eater. The slowness of perception is so great that, when one asks a question, before the purport of it has reached the woman's brain she forgets that she has been addressed. I happen to have seen eight cases of insanity as a result of the childbearing process—a large experience for an obstetrician, because they occur but once in about 400 childbirths. In these eight cases I have most frequently seen this peculiar mental state that I have seen under no other circumstances. I suppose a professional alienist would give it a proper name; I have been in the habit of calling it dementia. That term perhaps would not be allowed by the neurologist, but in default of a better I use it to distinguish it from melancholia.

In the study of a large number of women insane as the result of childbirth, it has been found that the maniacal type is the most common. But this conclusion is based mainly on the statistics of insane-asylums, to which maniacal cases are almost sure to go, while melancholic and demented women would more likely be kept at home. In my own experience, relatively small of course, I have seen mania in but 25 per cent. of the cases.

It is always interesting in these cases to investigate the causes, for there is almost always one to be found, and some of them should teach the physician a useful lesson. Dr. Fordyce Barker saw thirteen cases of obstetrical insanity in physicians' wives that he attributed mainly to the dread of parturition inspired by reading their husbands' books on midwifery. In one of my cases in hospital practice a violent mania broke out directly after the woman was informed by the resident physician, two weeks after labor, that the perineum was torn and must be stitched. I think there must be a predisposition to nervous break-down in individuals that develop insanity from comparatively slight causes. The lesson to be learned from such cases is to guard women of this character as far as possible from nervous shocks and strains, especially during pregnancy, recollecting that gestation adds immensely to the irritability and impressionability of the nervous system. In the majority of my cases the women were illegitimately impregnated, and brooded over their disgrace till they became insane, in two instances exhibiting a religious melancholia. In two cases the women were deserted by the men that married them. In another, the woman had lost an older child from diphtheria. There is always some exciting cause to be discovered. Fortunately, the prognosis of the disease is good. The women recover their reason in about two-thirds of the cases, and the death-rate is low. The fatal results are generally due to the sepsis that so often accompanies insanity after labor that it must be regarded as a cause, or less frequently as the result, of maniacal exhaustion.

THE CARE OF THE UMBILICAL CORD.

I wish next to give you a demonstration of the way to take care of the umbilical cord in a newly-born infant. Carelessness in this particular has brought about very

bad results. I myself have made five post-mortem examinations of infants dying from septicemia resulting from such carelessness. The old plan was to surround the cord with a greasy, very often dirty, rag, and to leave the dressing undisturbed till the cord had dropped off. As a result, the cord would undergo a process of putrefaction or moist gangrene, with the constant danger that poisonous germs might be swept into the general circulation through the umbilical vein or the hypogastric arteries. We can avoid this danger by a little care, just as we are able to prevent septicemia in our obstetric operations. Here is a typically healthy umbilical cord. It is dry, and black in color. There is here a dry gangrene, or mummification; we secure this result by dressing the cord antiseptically when the child is cleansed after its birth, and changing the dressing daily. In my own work I use salicylated cotton. A pledget is placed on the abdomen above the umbilicus, on which the cord is laid. Over the cord is laid another pledget, and the whole is held in place by an abdominal binder of soft flannel. Should there be some little putrefaction in spite of these precautions, we can neutralize its effects by dusting the cord with an antiseptic powder, the best being starch and salicylic acid, five parts to one. It is not usually realized by the general practitioner that septicemia in the newly-born baby is common. In fact, to the general practitioner the whole pathology of early infancy is often most obscure. If the child dies in the first week or two, a death-certificate is given with marasmus or inanition as the cause of death—indefinite terms that cover a vast multitude of interesting conditions.

MAMMARY BINDERS.

I have next to demonstrate to you a matter seemingly trivial, but in truth of considerable importance. It is a very common thing to see an exaggerated engorgement of the mammary glands when milk-secretion is first established. The consequent distention and swelling of the breasts gives the woman pain and exposes her to the danger of mammary inflammation, and possibly of suppuration. In this connection it is interesting to recall the steps by which we have reached our present knowledge of the formation of mammary abscesses. It was formerly thought that mammary abscesses came from "a caked breast." But when the bacteriologist demonstrated the true pathology of wound-infection there arose an ever-increasing class of physicians that believed mammary abscesses to be the result of an infected nipple. Later investigations, however, have shown that there was a good deal of truth in the old idea. There *is* a mammary abscess that results from the invasion of the glands by staphylococci from the deeper lactiferous ducts. For this to occur, however, it is necessary that the resisting power of the cells in this situation should be much reduced, and it is the great engorgement of the glands with blood and milk that thus paves the way for infection. There are two causes of mammary abscesses: the first, an infection of cracks and fissures in the nipple; the second, a reduction of the vitality of the epithelial cells deep within the breast, and their subsequent invasion by staphylococci. It is the old story of the gold and silver shield over again, to which we find so many analogies in medical disputes. A mammary abscess is, therefore, to be avoided by preventing fissures in the nipples, or by keeping these clean should they develop, and by preventing too great engorgement of the glands. The latter object is attained by the use of a mammary binder, and by the frequent evacuation of the breasts. On three successive patients I propose to show you some of the mammary binders that are in common use. I first exhibit one that I must unreservedly condemn. In this institution, however, it has obtained a firm hold. You see that it is a piece of unbleached muslin, wide enough to reach from the axillæ to the false ribs, and long enough to surround the chest, with two holes for the nipples. The single advantage of this binder is that the woman can nurse the child without the necessity of removing the binder. It has the serious disadvantage that the nipples, being the only parts of the breasts free from pressure, swell, become edematous, and crack. The mammary binders that I have found most useful are the Richardson binder, and the Murphy binder, devised by Miss Murphy, of the New York Maternity.

The binder of Richardson requires practice for its proper application. When properly applied, it is the best-looking binder that I have seen. I use it in one of the hospitals over which I have control, and the nurses there are skilful in adjusting it. In the hands of one unaccustomed to its use, the chances are that it will not be comfortable. This binder consists of a T-bandage folded and held by a safety-pin in the shape of a Y, the two arms of the Y surrounding the glands, and the single arm passing under the woman's back. In this way we get pressure from above and below, and obtain a firm and even support with comfort to the woman. You can see the effect of this mammary binder on the woman before you; you see how efficiently the binder must prevent engorgement; under its pressure the milk is running out of the breasts.

On another patient I show you the so-called Murphy binder. It is a solid piece of unbleached muslin with arm-holes, and a neck-hole V-shaped in front. This is undoubtedly the most generally convenient form of mammary binder. It can be made by any seamstress, and can be applied without any special skill. It compresses the breasts in all directions, squeezing them close together, and thus preventing engorgement. Had this woman well-developed mammary glands, you would see that they would be pressed so closely together as to be in actual contact, and that it would consequently be necessary to insert a layer of cotton between them to prevent friction and irritation of the skin. The second object of our treatment, the evacuation of the glands, is best obtained by the regular application to them of the best breast-pump there is, the infant's mouth. Should this be impossible, or, in rare cases, insufficient, the breasts must be emptied as often as necessary by massage, or by an artificial breast-pump, the best of the many on the market being the English.

RECTO-VULVAR FISTULA.

This patient whom I now show you has a recto-vaginal fistula, or rather a recto-vulvar fistula, of the kind of which I have spoken to you before, but due to a different cause. She was admitted to the hospital some four years ago with an abscess in one labium, which a few days before had broken spontaneously. From that time feces have passed partly by the vagina. There undoubtedly ex-

isted a collection of pus that, burrowing between the vagina and rectum, was discharged into the rectum and floor of the vestibule. This possibility is an argument for the early opening of an abscess in this situation. This woman, we find, has syphilis of an old date, and the edges of the fistula look like a chronic chancroid. There is a tradition in this hospital against operating upon cases of this kind. I once operated for this condition upon a syphilitic woman in the wards, not knowing the specific taint. The operation was performed with the utmost care, and I was satisfied with every point of it, but when I took the stitches out the whole was larger than at first. I operated again with a like result, so that after the second operation the woman's condition was much worse than it was before I had operated at all. I was thus convinced that the old tradition is correct, unless possibly by specific treatment the tissues are prepared for the operation. I intend to try this in the case before you. I shall administer mercury and iodide of potassium, and after a few weeks shall attempt an operation with some hope of success. Without such preparatory treatment the after-condition is likely to be worse than the first.

MAMMARY ACTIVITY AND MENSTRUATION IN THE NEWBORN.

I have here two infants, each presenting an interesting condition. You see that each presents a marked enlargement of the mammary glands, and that in the glands of one of them there is milk. To demonstrate this I squeeze the breasts; this is a bad practice, for the irritation thus produced might lead to inflammation and suppuration. It is a curious fact that in a large proportion of babies of both sexes we observe an engorgement and functional activity of the mammary glands between the fourth and the twentieth days after birth. I recall a case in which the enlargement equalled the size of a crab-apple, and out of the breasts a stream of milk ran across the chest. We cannot explain why this activity of the mammary glands should so early occur. It requires no treatment; indeed, in no way should the breasts be disturbed. The nurse may have an inclination to squeeze or manipulate the glands, with the mistaken idea that she can thus reduce the swelling, but this should be forbidden. In extreme cases a soothing lotion with inunction of the skin over the glands is called for. If an abscess should develop, it must be opened early, for a mammary abscess in a young infant is a more serious condition than in the adult; in such cases the mortality is quite high, as the pus has a tendency to break inward and infect the lungs. In one of these infants—a female—there was for a few days after birth a bloody discharge from the vagina, that has now ceased. In connection, apparently, with the activity of the breasts after birth, we sometimes see in the female an engorgement of the genitalia and a discharge of blood quite like the menstrual flow. About once a year I see a case of this sort, my attention being called to it by an alarmed nurse or mother, or sometimes by an astonished physician. When I first saw this phenomenon I too was very much interested, and endeavored to learn the source of the bleeding. Upon examination with a speculum improvised of two hairpins, I found the discharge coming from a point in the vagina higher than I could see, presumably from the uterus. Some time after this I saw in the *Transactions of the London Obstetrical Society* that a physician had had an opportunity of making a post-mortem examination in two cases, and had found the uterine mucous membrane in the same condition that it is in menstruation, and had discovered that the blood was oozing from this source. This condition also requires no treatment; the discharge ceases after a few days, and during its continuance the child does not suffer. It is a mistake to use astringent applications or even injections, a custom I have seen recommended, just as much so as it would be to use the same treatment in a menstruating woman. These phenomena seem to be closely allied—the action of the breasts and the discharge from the uterus after birth.

ARTIFICIAL FEEDING OF INFANTS.

I wish now to show you an interesting contrast between a baby that is as well developed as we could desire, and another about as ill-nourished as it could be and live. The child in the nurse's arms has been breast fed, and is the picture of a perfectly healthy infant; it weighs over twenty pounds. In contrast, here is this poor, miserable creature, that was brought into the house four weeks ago in a much worse condition than you now see it. This baby is about two months of age, and I presume was outrageously neglected outside of the hospital; it was fed from the bottle, and that usually implies ignorance and carelessness, if not actual neglect. When the child first came in I despaired of doing anything for it. But we put it on the system of artificial feeding at present in force here, and we have so far had a very satisfactory result. Since the child has been in the house it has increased in weight from five pounds and eight ounces to six pounds; it has gained half a pound. The food of this child has been condensed milk, water, and cream, and so long as it flourishes on this food we shall continue it. I trust we shall in time make of this miserable creature almost as healthy a child as is the other infant. Of course, when we start with such material we are seriously handicapped. Should any disease attack this child, it would be likely to succumb. You can have no better contrast between the ordinary result of feeding upon milk from the healthy mother's breast and the result of bottle-feeding as carried out by ignorant nurses and mothers. I shall have occasion to refer to this again in a later lecture.

About a year ago I devised a weight-sheet for infants in the house, which has been in use ever since; it is a very satisfactory method of observation. Each child's weight is taken daily and entered on this sheet, and by carefully studying the results we can form some opinion as to the relative merits of different kinds of feeding. The subject of artificial feeding is by no means definitely settled, but a solution can be reached only by this plan. The best method of artificially feeding young infants is to be learned with the help of organic chemistry, and must be demonstrated by clinical results. I shall in the near future devote a whole lecture to this subject.

LUMBO-SACRAL KYPHOSIS.

I have next to bring before you a woman seven months pregnant, with one of the most interesting deformities of the spine that I have ever seen in a preg-

nant woman. It is called lumbo-sacral kyphosis (see annexed illustration). The history of the case is as follows: This lump on her back first appeared nine years ago after having lifted a heavy weight. At the present time she is twenty-nine years of age, so that this deformity was produced in her twentieth year, and in consequence of its late occurrence it has not had much effect upon the size and shape of the pelvis; but had this accident occurred early in the girl's life, before the full development of the pelvis, she might have had an exaggerated degree of the deformed pelvis known as kyphotic. This woman has had one child, and experienced no difficulty in the labor. The only effect that the deformity of the spine has on her pregnancy and labor is to shorten the abdominal cavity, with the consequent production of a somewhat pendulous belly. As a result of the diminution in the perpendicular axis of the abdominal cavity, the child *in utero* lies transversely,

because in this position it finds greatest comfort. This may lead to a complication in labor by the presentation of the trunk of the child instead of one of the extremities, but very likely the first few labor-pains will right the malposition. From the surgeon's point of view, I would judge this to be a rare case. The luxation of the last two lumbar vertebræ here is apparently the result of a heavy strain, by which I presume the woman must have ruptured some of the ligaments of the spinal column. Injuries to the spinal column in which the force is exerted in the opposite direction result in what is called a spondylolisthetic pelvis, in which the last lumbar vertebræ, instead of slipping backward, slip forward and downward over the sacrum; but in this case, as the woman stooped over to lift a very heavy weight, the muscular force exerted was sufficient to spring the lower vertebræ backward. I cannot recall a similar case either in my reading or in my personal experience. This woman has the typical short, broad back that is seen in all humpbacks. In her case we shall do nothing but wait for the delivery at the normal termination of pregnancy, because we expect no greater difficulty than possibly a transverse presentation of the child. But it is astonishing how such cases correct themselves in this particular. I have seen the labors in four cases of marked humpback with true kyphotic pelvis. In three cases the transverse position of the child was corrected by the first few labor-pains, and the women delivered themselves without any more difficulty than is usually experienced by primiparæ. The fourth case, on the contrary, was one of the most difficult I ever had to manage. I first attempted craniotomy, but failed, and was compelled to do an immediate Cæsarean section, opening the abdomen and delivering the child before the woman recovered from the ether given for the first operation.

THE INDUCTION OF PREMATURE LABOR AT THE SEVENTH MONTH ON ACCOUNT OF A RHACHITIC PELVIS.

In the case I now bring before you, labor was induced in the seventh month of pregnancy. When the child was born it weighed only three pounds. It was placed in an incubator, in which it remained about a month, and is now, at six months of age, as healthy and hearty as any baby you could find. In this case the indication for the induction of labor was a high grade of contracted pelvis. It was one of the most contracted pelves that we have seen in Blockley for a long time. The delivery occurred in the service of one of my colleagues, who is to be congratulated on the good management of the case. I shall measure the pelvis before you, that you may see the practical application of pelvimetry, and may hear the interesting measurements as I make them. They are as follows:

Iliac spines	24.50 cm.
Iliac crests	24.00 "
External conjugate, Baudelocque's .	15.50 "
Internal " diagonal . .	9.25 "
True " estimated . .	7.00 "
Right diagonal	19.00 "
Left "	19 00 "
Circumference of pelvis . . .	71.20 "

These measurements show at once that we have to deal with a rhachitic pelvis, generally contracted as well as flat. This is shown by the relationship between the spines and the crests of the iliac bones. In addition, there is an interesting point here confirmatory also of the diagnosis of rhachitis; I find the depression beneath the last spinal process of the lumbar vertebræ almost on a line with the posterior superior spines of the ilia. In almost every well-developed female one can actually see the relationship between these three points. The depression below the last lumbar spine is well above the two dimples marking the posterior superior spinous processes of the iliac bones, so that these points with the beginning of the fold between the nates make a lozenge-shaped, or rather a kite-shaped, figure. This can be seen in the Capitoline Venus, and in many other statues of antiquity representing perfect women. In a rhachitic woman, on the other hand, this figure is almost or quite a triangle with the base above and the apex below. Moreover, on vaginal examination, I find in the case before us a very marked promontory, and a very marked increase in the conjugato-symphyseal angle, another symptom of rhachitis, so that we must subtract at least 2¼ cm., if not a trifle more, from the diagonal conju-

gate to get the true antero-posterior diameter of the superior strait, making the latter not more than a scant 7 cm. This woman is very fortunate to have escaped, as she did, with a comparatively easy labor, and to have a child that has grown up so well. It was wise to resort to the induction of labor so much before the usual time. The success of the treatment for the interruption of pregnancy in cases of contracted pelvis demonstrates the advantage of this plan of managing pregnant women with contracted pelves, and shows the importance of always carefully considering this method of dealing with such cases before one decides upon Cæsarean section. In the present rage for abdominal operations that possesses so many surgeons, an unnecessary Cæsarean section is only too likely in a girl like this. Medical literature in the last few years contains not a few cases in which Cæsarean section was performed on much slighter grounds than we had in the present case.

A DEEP WOUND IN THE VAGINAL VAULT, OF MYSTERIOUS ORIGIN.

The next patient is a woman that, about a week ago, was brought in bleeding profusely from the vagina. She gave us the history that the bleeding had commenced about ten o'clock on the previous night. She was so profoundly reduced by the loss of blood that it was a question whether she could be saved or not. Her feet were placed higher than her head, the pillow removed, and the bleeding fortunately ceased spontaneously. The woman's temperature at first was so low that the thermometer would not register. When I first saw her, a few hours after her admission to the house, there was no more bleeding, but there was still a low temperature—96°—and a weak, rapid pulse. I placed a large tampon in the vagina, and ordered restoratives and stimulants. On the following day I made an examination, and, after a careful search, found the origin of the hemorrhage in a lacerated wound in the upper vaginal vault, a little to the left of the cervix, an inch or more in depth, and in its broadest part about half an inch across. I also found the posterior surface of the cervix raw, as if some rough instrument had been scraped over it. I questioned the woman closely as to the cause of this wound. She could give me no explanation of it whatever; she denied everything that might possibly account for it, but we had the evidences of our own senses. There was the freshly-made rent with ragged edges. We still remain in doubt as to the cause. I suspected at first it had been due to violence in coitus. Again, I suspected that the woman had been introducing something into her vagina, probably with the idea that she was pregnant, but she denies this absolutely. I think that the woman is keeping the truth from us, and that the injury was either inflicted in coitus or with an instrument of some sort. We gave the patient daily injections of an antiseptic fluid and tamponed the vagina. She is picking up very rapidly, and in a few days will probably leave the hospital. I would like very much to get a true history from her before she goes. If the wound was the result of violent coitus, it is a very rare case, and it is uncommon enough if it is due to the use of an instrument. The hemorrhage did not come from the womb at all. The uterus was firm, and the cervical canal tightly closed.

This shows you how little dependence can be placed upon the history of some gynecological cases. Had I relied upon the woman's statements, I would have been forced to believe there was probably a cancer of the womb or vagina; but, relying upon the evidences of my own senses, I can only ascribe it to one of the two causes mentioned.

CLINICAL MEMORANDA.

A CASE OF PUERPERAL SEPTICEMIA.

BY W. O. HUSTON, M.D.,
PENINSULA, OHIO.

THE symptoms and temperature-course in some cases of puerperal fever and pelvic abscess bear a striking resemblance to those of malarial fever. In the case of puerperal fever here reported the course of the temperature was erratic and deceptive.

Mrs. H., a primipara, twenty-three years old, was at term, by means of the forceps, delivered of a child that was apparently but recently dead. Strict antiseptic precautions were observed in the accouchement. The perineum was not ruptured.

On the evening of the second day the woman's temperature was normal; her pulse was 60. The only source of trouble was retention of urine.

On the third day the pulse was 100, temperature 99°.

On the fourth day the pulse was 116, temperature 101°.

I syringed the cavity of the womb with a quart of warm 1 : 40 carbolized water on the night and morning of the fifth day. The temperature was from 101.5° to 102°; the pulse 116. The evening douche was followed by a prolonged rigor lasting about an hour.

On the sixth day the temperature was 102.6°; the pulse 118. By means of a dull curette and a polypus-forceps, I removed a quantity of clots and shreds of membrane and placenta, from which emanated a slightly foul odor. Subsequently I applied a douche of mercuric chloride 1 : 3000. A rigor followed lasting about ten minutes.

On the following day, the seventh, the pulse was 105; the temperature 101° A.M., 100° P.M. During the night a sharp attack of diarrhea set in, to which, on the morning of the eighth day, were added distinct evidences of peritonitis. The pulse was 120; the temperature 103.4°. I kept the patient partially narcotized with morphine. I again curetted the uterus, removing a few clots devoid of foul odor. The lochia were apparently normal and at no time suppressed. There was an abundant secretion of milk. The abdomen was moderately tympanitic and tender. During the night the pain was so severe as to require the repeated administration of a third of a grain of morphine.

On the eighth day the morning temperature was 104°, the noon temperature 102.5°, the evening temperature 101.5°. The douches were discontinued. Dr. W. A. Knowlton saw the case in consultation and advised a continuation of the treatment, which had included quinine, iron, and whiskey in large doses, with morphine and occasional minute doses ($\frac{1}{10}$ grain) of calomel.

On the ninth day the morning temperature was 102.5°, the evening temperature 100°. The perspiration, which had been free since the third day, was now quite profuse.

On the tenth day the morning temperature was 101.5°, the evening temperature 99.5°

On the eleventh day the morning temperature was 100°, the noon temperature normal. At about 4.30 P.M. the temperature suddenly rose to 105°, the patient gasping for breath. Ten grains of phenacetin in two hours reduced the temperature to 102.5°.

On the twelfth day the morning temperature was 103.5°, the afternoon temperature 101.5°.

On the thirteenth day the morning temperature was 102.8°, the afternoon temperature normal. Fearing the development of a pelvic abscess I made a careful examination and found the uterus tender, hard, and enlarged, but could detect no deposit about it.

On the fourteenth day the morning temperature was 102.6°, the evening temperature normal.

On the fifteenth day the morning temperature was 102.4°, the evening temperature normal.

On the sixteenth day the morning temperature was 102.4°, the evening temperature 98°.

On the seventeenth day the morning temperature was normal, the evening temperature 102.2°.

On the eighteenth day the morning temperature was normal. Thenceforth the temperature continued normal until the twenty-first day, when it rose to 102.5° for a few hours, again to fall permanently to the normal. Convalescence was now rapid.

One peculiarity about the temperature in this case was the frequency with which it rose in the morning and fell at night, sometimes to normal. The temperature was apparently uninfluenced by quinine, which was given every two or three hours during the day and night, at the rate of from eighteen to seventy-two grains in twenty-four hours, according to the urgency of the symptoms. The largest quantity never depressed the temperature more than one or two degrees. Here was a picture suggestive of remittent and intermittent fever: rigors, fever, sweating, intermissions with exacerbations at times sudden and unexpected.

As to the source of the infection in this case, I have already indicated that the hands and instruments were carefully disinfected. I had not attended a case of contagious disease or held a post-mortem for several weeks. The attendants were neat and clean. The surroundings were good. The recent death of the child would preclude the possibility of infection from that source. The Credé method was employed in the removal of the placenta and the membranes were twisted so as to bring them all away; nevertheless a number of fragments of placenta and membranes were removed with the clots, although their odor was scarcely offensive. In how many thousand cases do like conditions prevail without any evil result. There was no laceration of cervix or perineum.

Dr. W. T. Lusk, a few months ago, in reporting a case of puerperal septicemia seen in consultation, after searching in vain for a cause, finally hit on a foul water-closet, which the woman had several times used before confinement. It occurred to me that if such were the case, why do not more women living outside of the cities have puerperal fever, for they are all compelled to use foul privies.

One point more. During the progress of this case I attended three other women in confinement. Before visiting them I bathed my whole body in a 1 : 2000 solution of mercuric chloride and changed all my clothing. All three cases did well.

A CASE OF ACUTE INTERNAL STRANGULATION OF THE BOWEL IN A CHILD TWO YEARS OF AGE; LAPAROTOMY; DEATH.

BY W. L. SCHAEFER, M.D.,
OF RIDGEVILLE, OHIO.

IN September I was asked to see H. B., two years old, who, the parents told me, had been well until the day before, when he was suddenly seized with colicky pains in the abdomen. In the course of two hours vomiting set in. The vomited matter at first consisted of the contents of the stomach, afterward of bile, but it soon became stercoraceous. The countenance assumed an anxious expression; the eyes were sunken; the pulse was frequent and feeble; the temperature was normal. The child manifested great thirst, but the fluid taken was almost immediately returned. A movement of the bowels took place, the stool consisting principally of mucus, and containing no blood. The abdomen was tympanitic, but no tumor could be detected. Four grains of the mild chloride of mercury, with five grains of bismuth subnitrate, were administered, but were not retained. The vomiting continuing, injections of warm water were given on the following day. These were retained for a while, but brought away no feces. An ounce of glycerin was injected, but soon returned.

The colon was filled with water, but with no result. As a last resort, air was injected by means of a small pair of bellows. This but increased the distention of the abdomen, and greatly added to the distress of the little sufferer.

A day later the abdomen was still greatly distended, and somewhat tender. The peristaltic contraction of the small intestines could be plainly seen through the abdominal walls. The temperature was 101°. As it had become night, I gave one twenty-fourth of a grain of morphine sulphate.

On the following morning Dr. Henderson, of Waynesville, saw the case with me, and abdominal section seemed to offer the only hope. The parents having consented, with the assistance of Dr. Ward, of Lytle, I operated in the afternoon. On opening the abdomen by a median incision, the bowels were found so greatly distended as to obstruct and hinder manipulation. There was no evidence of peritonitis. The obstruction was found to depend upon a complete twist of the small intestine, about four inches above the ileo-cecal valve. The gut between the twist and the ileo-cecal valve was completely collapsed, showing that neither air nor water had passed the valve. The gut was carefully untwisted. It was dark and deeply congested, but not gangrenous. The peritoneum was brought together by buried sutures of fine iron-dyed silk.

Sufficient superficial sutures were placed in the abdominal walls to accurately approximate the cut surfaces, and powered iodoform was dusted over the line of incision. Absorbent cotton and a bandage completed the dressing. The usual antiseptic precautions were observed. When the patient emerged from his anesthesia he was snugly wrapped in a hot blanket, placed in bed, and given a small dose of morphine, one-thirtieth of a grain, with a little whiskey. Reaction, however, failed to set in, and the patient gradually sank, and died two hours after the operation.

REMARKS.—While the result in this case was bad, there are some lessons of practical value to be learned from it. I think that we waited too long, trusting to other means, namely, cathartics, enemata, injections of air and water. One point that was clearly brought out was the irrefutable evidence afforded by the collapsed condition of the gut, between the ileo-cecal valve and the seat of strangulation, that neither air nor water passed the valve.

ANTIPYRIN IN WHOOPING-COUGH.

BY W. A. DEWOLF SMITH, M.D.,
SURGEON TO THE BRITISH COLUMBIA PENITENTIARY, NEW WESTMINSTER, B. C.; VICE-PRESIDENT OF THE B. C. MEDICAL COUNCIL.

THE unsatisfactory nature of the treatment of whooping-cough is easily seen by looking over any article on the subject, or by consulting Neale's *Medical Digest*, where a list of remedies is given taking up a full page and a half of that book.

Almost any remedy in the Pharmacopœia (and many out of it), from charming by a seventh son to vaccination, and from aconite to tar, seems in some hands to have produced good results. The list includes almost every class of remedy—sedatives, tonics, alteratives, antiseptics, and stimulants, and even flagellation has been recommended for it, but fortunately without meeting with any very general acceptation.

During the earlier days of antipyrin much was written in its favor, and it was held up as almost a specific in whooping-cough by Sonnenberger;[1] Griffith,[2] who followed Sonnenberger's method; Genser;[3] Dubousquet-Labordière;[4] and Tordeus, of Brussels,[5] who all obtained good results from it; and more recently a writer in THE MEDICAL NEWS[6] advances the claims of antipyrin.

It must not be forgotten, however, that there is another side to the question, for other observers have found that it either had no effect in controlling the spasms, or that it had positively harmful effects. Amongst those that have not had good results from antipyrin are Monti (of Vienna),[7] Baginsky, and Tuczek, the two last mentioned having seen alarming effects from its use.

My own experience with the drug has been limited to about ten cases during the last three years, and although I have not seen any harm come from its use, the effects in each case were negative. The cases ranged from one to twelve years of age, and were first seen in an early stage of the disease. The remedy was given after Sonnenberger's method—*i. e.*, a dose graduated according to the age of the child. In no case could I see that the disease was at all shortened in its course, nor was there any difference in the severity of the complaint when the remedy was stopped after having been administered for some days.

It is quite clear, therefore, to my mind, that although we have in antipyrin a most valuable remedy in certain forms of disease, its claim to rank as a specific in whooping-cough is not yet established on a sure and certain foundation.

MEDICAL PROGRESS.

An Unusual Neurosis.—HELMUTH (*Casopio Ceskych Lékaru*) has reported the case of an unmarried, intelligent teacher, twenty-five years old, with no neurotic family history. Menstruation was regular in time but protracted in duration, and always accompanied with pain. Following an injury to the left eye from a broken violin-string, it was noticed that reading readily caused annoyance. On examination no lesion of the eyes could be detected. There was considerable headache. Soon it was observed that on excitement or emotion the left half of the face flushed and became warm, and in the course of two or three seconds the left side of the head and face became the seat of profuse perspiration; the left ear became purple, and from the auditory canal there flowed an aqueous discharge. There was a sense of fulness in the left nostril. At the same time the right side of the face became pale, dry, and cold. If the provocation was intense, the left arm up to the elbow-joint became red, but without perspiration. The phenomena were aggravated during menstruation. Improvement took place as menstruation was regulated and existing constipation was overcome. Iron and aloes were the medicaments employed.

Inflammation of the Vas Deferens Without Epididymitis.—MAURIAC (*Annal. de Dermatol. et de Syphil.*, No. 6, 1891) has recorded the case of a man with gonorrhea and cystitis, who, on the thirty-third day of the disease, after a long journey on foot, was seized with severe pain in the hypogastrium. After the pain had been relieved by the application of ten leeches, the prostate, by rectal examination, was found to be normal. The vesicula seminalis, however, was represented by a small, hard, enlarged mass, while the vas deferens was also hard, enlarged, and painful. The internal opening of the inguinal canal acted as a barrier to the extension of the inflammation, and epididymitis did not develop. In all his experience Mauriac had not previously observed inflammation of the vesicula seminalis and of the vas deferens, without funiculitis and epididymitis.—*Deutsche med. Wochenschr.*, No. 44, 1891, p. 1232.

Recovery from a Tumor in the Region of Right Crus Cerebri.—THOMSON (*Edinburgh Medical Journal*, September, 1891) recently presented to the Edinburgh Medico-chirurgical Society a girl, six years old, who fifteen months previously, when she was presented to the society, displayed paresis of the left side of the face and of the left arm and leg, paralysis of the muscles supplied by the right third nerve, slight optic neuritis, and marked mental dulness. With careful feeding and the administration of cod-liver oil and iodide of iron, the palsy had moderated; slight dilatation and sluggishness of the right pupil remained; the neuritis had disappeared; the mental condition had improved; and there had been a gain in weight and strength. The lesion was considered as a tuberculoma in the region of the right crus cerebri.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

THE ELIMINATION OF THE DANGERS CONNECTED WITH MILK-SUPPLY.

THE economic and sanitary advantages of milk-inspection cannot be over-estimated. As commonly practised, adulteration consists either in the addition of water or in the removal of more or less of the cream, or in both. The effect of lowering the nutritive value of an article that enters so largely into human diet, that is so much depended on in the sick-room, and that is so universally used as food for infants, can be readily comprehended.

The law directs that only pure milk shall be sold, and yet the means of accomplishing this object fail in some most important particulars. Milk may be the vehicle of conveying the poison of disease. It has been proved beyond doubt that the *materies morbi* of enteric fever, of scarlatina, and of diphtheria has been conveyed through this medium; and it is extremely probable that tuberculosis can be transmitted in the same way. The tests ordinarily applied to milk fail to detect the specific germs of these diseases.

Chemical analysis, though of the greatest advantage in accurately determining the composition of milk and in detecting adulteration, is unable to discover the living pathogenic entities, which are the more dangerous because of their power of directly producing disease. In order, therefore, to guard against this subtle danger, and in order to render milk-inspection a positive protection, it is necessary to resort to other methods of investigation. Fortunately, in biologic examination we have a valuable means of supplementing chemic analysis. If biologic examination were only occasionally the means of detecting the tubercle-bacillus in milk, the discovery would be of sufficient value to compensate for the investigation, for by it the dairy-farm from which the milk was obtained could easily be discovered, and the diseased animals that day after day caused the milk of an entire herd to be infected could be promptly destroyed.

But the investigation need not be confined to tuberculosis. Biologic science has made rapid strides, and is constantly adding to our knowledge of the rôle played by microörganisms in the causation of disease. This knowledge, whenever practicable, should be made use of in conserving the public health.

Both chemic analysis and biologic examination have their special and well-defined fields of exploration. When one fails, the other may be able to make valuable discoveries. Their office is to aid one another, and supply each other's deficiencies. Hence, the best results are to be obtained when the two methods of examination are combined.

Another means of protection, and a most important one because it strikes at the source of contamination, is the systematic inspection of dairy-farms, dairies, and milk-shops. This practice is required by the English law and to some extent is carried out, but in America it is almost entirely neglected. Milk may be contaminated by the addition of impure water in the milk-houses, and is frequently adulterated after it leaves the dairy-farm; but the most dangerous source of contamination is at the dairy-farm itself. For this reason, inspection is very incomplete that does not include a watchful supervision of the cattle, their environment and treatment, and all the conditions under which the milk is prepared for the market. The seeds of tuberculosis lie concealed in what to all appearances is wholesome milk, and who can tell what amount of disease is distributed through the unsuspected agency of this common article of food? There is less likelihood of infection from anthrax or

malignant pustule, and foot-and-mouth disease, as self-interest prompts the dairyman to quickly exclude from his herd animals sick with these diseases.

It has not been determined whether or not the milk of cows suffering from actinomycosis, caused by malignant ray-fungus, is capable, through its ingestion, of propagating the disease, but until this point is decided the milk should be rejected as suspicious. We have known cows suffering from this affection to be milked for a season, and then turned over to the butcher for slaughter—a practice that is reckless if not positively dangerous in its ultimate results. MR. ERNEST HART has tabulated a number of epidemics of enteric fever, scarlatina, and diphtheria that have been definitely traced to milk infected at the dairy-farm. The milk of cows fed on distillery waste, or that are sickly or in bad condition from unsuitable food, impure water, bad housing and care, or that have recently calved, cannot be regarded otherwise than with suspicion. Milk is known to have been infected by the hands of the milker convalescent from scarlet fever. Typhoid fever has been propagated by the use of infected water for rinsing the milk-cans and diluting the milk.

It is seen that the liability of contamination to which milk is exposed at the place of collection is very great and constitutes the chief source of danger, especially so as most of the elements of danger may escape detection by the ordinary methods of laboratory investigation. Hence the necessity of establishing systematic inspection of all dairy-farms as well as of milk-shops by competent officers amply clothed with authority to compel the observance of regulations for their proper sanitary administration.

It is important that none but healthy cattle should be permitted in the herd. Cows affected with tuberculosis or other dangerous infectious or contagious diseases should at once be isolated or destroyed. Pure water is quite as essential to the health of animals as is wholesome food. Special attention should be directed to the housing of the cattle. Cleanliness and ventilation are most important requirements. The possibility of contamination of the water-supply from any source, especially by the cesspool, is to be carefully guarded against. The greatest cleanliness is to be observed in collecting and in handling the milk.

Should contagious disease break out in the dairyman's family, he should be prepared by previous instruction to guard the milk-supply from this source of danger. Printed instructions covering the management of the dairy-farm should be supplied to the farmer, and the inspections should be sufficiently frequent to see that the instructions are faithfully carried out. By adopting the plan thus briefly outlined, in conjunction with the tests usually applied to milk when delivered in the city, there is the assurance that the milk-supply will be most effectually guarded against adulteration and contamination.

The inspection of dairy-farms should be conducted under the provisions of a law applying to the whole State. Cities obtain their milk-supply from surrounding and even distant counties, in territory lying beyond their jurisdiction, and they are therefore powerless to exercise the necessary supervision. This is also true of towns and villages, though in the case of these there is less difficulty in obtaining information with regard to the source of the supply. In the absence of a general law, protection might be secured by permitting the sale of milk under license by those producers only that submit a satisfactory certificate of inspection of their herds and farms made by qualified persons at such stated periods of time as may be determined upon. The details of inspection should cover the matters of investigation already pointed out, and the reliability of certification should be subject to proof.

WORK OF THE DREXEL INSTITUTE.

THERE are few tendencies or facts that more continuously and exasperatingly act as brakes to medical progress than popular ignorance of physiology, hygiene, and sanitation. It is to this ignorance that quackery of a thousand types, the patent-medicine shame, and medical obscurantism, owe their vogue. Every agency, therefore, that looks to dispelling this ignorance must be hailed with delight by the medical profession. The establishing of departments of hygiene like that of the University of Pennsylvania is prophetic of the great science of preventive medicine, of which the University Extension movement, bacteriological laboratories, gymnasia, etc., are glimpses and promises.

But to those that would grapple with the real evils of life it has always seemed strange and profoundly sad that democratic education seemed fatally prone to imitate the useless virtues, decaying graces, and luxurious superfluities of aristocratic para-

sitism. The daughter of the mechanic was taught piano-thrumming, embroidery, or rhetoric, instead of potato-cooking, dressmaking, or household economy. The dream of the young lady's brother was to be sharp-witted, get "a pull," get ahead, and learn the wasteful vices of fashionable loaferdom. It is, for example, quite impossible to estimate the disease-producing power of the universal scorn of the art of cookery—an art upon which our physical health and more than physical happiness instantly and continuously depends.

In that splendid proof of modern heroism, the "Drexel Institute of Art, Science, and Industry," it is most gratifying to find that the physical and physiological, the intensely practical problems and needs of life are clearly seen, met, and provided for. To take a single instance: according to the *Preliminary Circular of Information* issued by the Institute—"The department of Domestic Economy will offer a liberal course of instruction and training for girls and young women in everything pertaining to the organization and management of the household. It will be thoroughly practical, while aiming to broaden the culture of young women in directions that have been heretofore neglected in their general education.

"The course will extend over two years, and will embrace cookery, millinery, and dressmaking, the building, sanitation, decoration, and management of the house, household economy, human physiology and hygiene, business forms and accounts, free-hand drawing, elementary economics, and physical training."

The course in cookery consists of instruction in the most practical details, beginning with the making and care of the fire, and ending with the chemistry of foods. There is a collection of food-products and preparations as an auxiliary of the course. The department of Physical Training will give opportunities for the physical culture of girls and young women, children and adults, lectures on personal and public hygiene, etc.

THE OBSOLESCENCE OF MEDICAL TERMS.

THE suggestion to abolish the use of the word phthisis, at least in its application to tuberculosis of the lungs, is both practical and progressive. First introduced to designate conditions attended with wasting, its application gradually became restricted to the commonest condition of which wasting is a most conspicuous manifestation, and for which phthisis then became a synonym—pulmonary tuberculosis. There are few dissentients to-day from the doctrine of the unity of phthisis, and those few will have to adopt some more distinctive name if they decline to accept that in common employ. There is now no further need for the word phthisis, and as a useless term it should be rooted out of medical nomenclature.

A somewhat analogous transformation is illustrated by the varying employment of the word apoplexy. First used to designate the sudden loss of consciousness that results not only from cerebral hemorrhage, but also from thrombosis and embolism, it subsequently became synonymous with the most common of these conditions—hemorrhage. Then its application was extended until hemorrhage into other viscera was also spoken of as apoplexy. Thus hemorrhage into the lungs became pulmonary apoplexy. There is now no further use for the word apoplexy, except as descriptive of a condition that is but symptomatic.

There is one other word that is most opprobrious, and that should be relegated to the obscurity that gave it birth—the word cancer. There was a time when the histological structure of neoplasms was even less well understood than it is to-day. Then all malignant growths were considered cancerous—and we fear that even to-day the careless and the uninformed are indifferent in their designation of such growths. With the creation of the word carcinoma there is no further necessity for the word cancer. The one can never be misunderstood, the other is vague, and bespeaks lack of precision.

Let us henceforth refrain from saying phthisis, apoplexy, and cancer, when we mean pulmonary tuberculosis, hemorrhage, and carcinoma.

MEDICAL ASPECTS OF COAL-BURNING.

LONDON has been shut in more than midnight darkness by a fog more dense and persistent than ever experienced before. People could not see their hands before their eyes in mid-day. Great suffering, thousands of accidents to life and health, have occurred, and the "smoke-nuisance"—the origin of the fog-nuisance—has become a matter of national medical concern. According to scientific calculations about 100 tons of soot fall upon the 110 square miles of roofs and streets of London each day. The number of fogs is constantly increasing, just in pro-

portion to the consumption (or, to speak more correctly, the non-consumption) of coal. Between six and seven million tons of coal were burned in the metropolis in 1890. Fogs in cold weather are invariably accompanied by a rise in the death-rate. Of course, to some extent, even in our country we are running the same race, and, though less possible of estimation, our death-rate must constantly be affected by the same cause. If, as certainly is true, sunshine is necessary to healthy life, human as well as vegetable, it becomes more and more imperative that mechanical ingenuity and sanitary science must teach our legislators how we may stop a million chimneys from belching forth into the atmosphere thousands of tons of black clouds of unconsumed carbon—a wretched pecuniary waste, but a still more pernicious squandering of health and life.

CORRESPONDENCE.

AN EASY METHOD OF ESTIMATING THE PERCENTAGE OF ALBUMIN IN URINE.

To the Editor of THE MEDICAL NEWS,

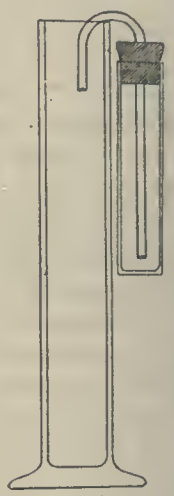
SIR: In THE MEDICAL NEWS of December 19, 1891, is a letter on the "Maximum Percentage of Albumin in Urine," which calls attention to the confusion and inaccuracy of statements in regard to the proportions of albumin in urine. The only accurate method of determining the percentage of albumin in urine or in other fluids is to separate the albumin and then carefully wash, dry, and weigh it. This process is tedious, and often impracticable. The general practitioner needs a short and easy method that is fairly accurate, and it is most desirable that some such method should be generally adopted. I have been in the habit of using a simple and rapid process that yields comparative results that are sufficiently accurate for practical purposes. While I make no claim to novelty in the procedure, the fact that there is no single method in general use leads me to describe it as one that is convenient and that requires no special skill or dexterity.

I have had constructed a tube, of which the accompanying drawing (Fig. 1) represents about one-fourth of the actual size, with an arbitrary graduation up to 100. In a test-tube of convenient size, I boil a little more than half a fluidounce of urine, to which have been added four or five drops of ordinary acetic acid. If the urine be turbid, it may be filtered before being boiled. After thorough boiling and allowing the urine to cool for two or three minutes, it should be well shaken, in order to divide the precipitated albumin as finely as possible, and then the graduation tube is fitted to the 100 mark. After twelve hours' standing, the percentage of precipitate is noted. The albumin will settle in twelve hours, and the volume of the deposit is not sensibly diminished if it be allowed to stand for twenty-four hours. The proportion of albumin measured in this way should be called *the percentage in volume of undried albumin.*

This method is not exactly accurate, but it is sufficiently so for ordinary purposes. It will indicate fairly well a proportion of 1 or 2 per cent. of albumin. When the proportion is less than 1 per cent., the ordinary method by contact or by simple boiling with a few drops of acetic acid would indicate "a trace" of albumin.

FIG. 1.

FIG. 2.



While writing upon this subject, I am led to describe a simple apparatus for detecting the presence of sugar in the urine, when the results of Fehling's test are uncertain. The accompanying drawing represents the apparatus one-fourth size. A small straight bottle or a small test-tube is fitted with a cork, through which is passed a small tube that reaches nearly to the bottom. The glass tube is bent so that the apparatus will hang over an ordinary test-tube or other convenient vessel. (Fig. 2.) The bottle is completely filled with urine, with which a piece of Fleischmann's yeast, about the size of a pea, has been thoroughly mixed. In putting in the cork, it is necessary to be careful to exclude every bubble of air. If the apparatus be kept for a half-hour at a temperature of from 80° to 90° F., a bubble of gas will appear if sugar be present in the smallest quantity. The apparatus may be placed in the sun or near a heater, but the temperature should not be higher than 100°. This is valuable as a negative test. In case of doubt I have often been able to determine absolutely the presence or absence of sugar before I had finished taking the history.

Procedures for the examination of urine, to be available in ordinary practice, must be short and easy, requiring little time and no great skill in manipulation, otherwise examinations that may be important will be neglected.

In the hope of contributing something to the needs of the busy practitioner, I have ventured to make this communication. With the method I have described for the estimation of the percentage of albumin, Doremus's

ureometer for determining the proportion of urea, and Roberts's "differential density" process for quantitative analysis for sugar, a chemical examination of the urine sufficiently complete and accurate to meet the requirements of most cases, is easily within the reach of every physician. Sincerely,

AUSTIN FLINT, M.D.

14 WEST THIRTY-THIRD STREET,
NEW YORK CITY.

TENDON-LENGTHENING BY SPLITTING, ETC.

To the Editor of THE MEDICAL NEWS,

SIR: As regards details of cases of lengthening of tendons by splitting them, etc., after the method recommended by Dr. Rhoads, I beg leave to state that, according to the enclosed copy of the German Hospital Records, I operated January 13, 1888, exactly according to Dr. Rhoads' method, on the contracted flexor tendons of the forearm of C. F., a girl twenty-two years of age, giving her a useful hand. I enclose a diagram also copied from the Hospital Record-book.[1] I performed the same operation some time before this, however, in a case of pes varo-equinus, and lengthened the tendo Achillis, but I have no notes of the case. I also operated in this manner on October 25, 1888, at the Presbyterian Hospital of this city, for the same defect. It was a case of pes equino-varus with contraction of the tendo Achillis in a girl eighteen years of age. Arthrodesis was done at the ankle-joint and Chopart's articulation, and the tendo Achillis lengthened in precisely the same way as recommended by Dr. Rhoads.

The idea was familiar to me, though I fail to find the method in any of the text-books in my possession. But do not doubt that somewhere an older communication to that effect must exist.

Allow me here to mention and recommend another method that, in suitable cases, will be found useful, and one that I have practised (if I am not mistaken) since 1884, my first case being one of lengthening the quadriceps tendon in an old fracture of the patella. It consists in cutting across the tendinous portion within its connection with the lateral fleshy muscular tissue. The latter will allow of considerable stretching, and in this manner the continuity of the organ will be preserved while lengthening is achieved, the degree of which, of course, varies in different muscles. In a contraction of the flexors of the forearm I found a combination of both methods very useful. I also combined this method with the flap method (reflected flap) in a case of injury to the extensors of the wrist, in which an extraordinarily wide gap existed between the stumps of the tendons four weeks after the original injury.

I do not know whether anyone before me has put this same idea into practice. At all events it seems not to be known, and I would like to mention it here, hoping that it may be useful and of benefit to patients.

I remain, yours very respectfully,

F. LANGE, M.D.

NEW YORK.

[1] Not reproduced because illustrating essentially the same method of operation as recommended by Dr. Rhoads and others.—ED. MEDICAL NEWS.

PHENACETIN IN THE TREATMENT OF INFLUENZA.

To the Editor of THE MEDICAL NEWS,

SIR: It is of great advantage to have at hand a remedy upon which one can place reliance, particularly for those diseases in which the onset is rapid and is attended with intense pain and hyperesthesia and considerable nervous derangement, the temperature mounting up to 102° or 103°, as is the case in influenza. Such a remedy will have enhanced value if it be quick in action, and if it can be employed without injury to patients. These advantages belong to phenacetin and sodium salicylate, which I have used in combination in a considerable number of cases of influenza with the happiest results. I have found the combination rapid, safe, and certain in action. I prescribe 5 grains each of phenacetin and sodium salicylate with 2½ grains of sugar of milk, the first two doses to be taken at an interval of two hours, and the subsequent doses to be taken at intervals of three hours. A laxative is given, if required. Attending bronchitis, pneumonia, either croupous or catarrhal, or other complications, while not a contra-indication to the employment of phenacetin and sodium salicylate, should be treated in the usual manner.

The method of treatment outlined may elicit criticism and be condemned as dangerous, particularly by those who have not employed it. I have, however, found it safe. I have employed it in the cases of childen as young as nine months, as well as in adults advanced in years. I do not advise the reckless and indiscriminate use of phenacetin; but, given intelligently and watched carefully, I consider it not only a safe, but a most valuable remedy. When necessary, stimulation may be added to the treatment.

Respectfully,

S. RUSH KETCHAM, M.D.

PHILADELPHIA.

THE TREATMENT OF HEMORRHAGE IN TYPHOID FEVER.

To the Editor of THE MEDICAL NEWS,

SIR: I wish to enter a protest against the usual and generally-accepted treatment of intestinal hemorrhage in typhoid fever. My last few cases, having ended in recovery, without medication, encourage me to believe that my previous results (about 50 per cent. mortality) in this alarming accident, were due to hypermedication. The hemorrhage has usually ceased by the time that its occurrence is recognized.

The remedial agents usually employed are ergotin, tannic acid, plumbic acetate, and opium. The hypodermatic injection of ergotin causes, first, a lowering of the arterial pressure, which is soon followed by an increase of pressure, so that ergot, if not harmful, is at least of doubtful utility. I have seen two cases of gangrene of the toes in the course of typhoid fever in which ergot had been administered.

A popular and favorite prescription for intestinal hemorrhage in typhoid fever contains tannic acid, tincture of opium, turpentine, and chloroform. The tannic acid is presumably selected for its local effect in traversing the intestine, or for its conversion into gallic acid in the circulation. The astringent effect can at best be but

slight. The tincture of opium is anti-peristaltic, but it is questionable whether muscular paralysis is desirable. Would one administer opium after labor or abortion, when the uterus is filled with clots that may become septic? In typhoid fever the putrid sloughs in the intestine are a source of infection.

Respectfully, John Rodman, M.D.

Abilene, Texas.

SPECIMENS OF URINE DESIRED.

To the Editor of The Medical News,

Sir: I am exceedingly anxious to obtain specimens of urine from cases of typhlitis or appendicitis, in order to determine, by an examination of this fluid, if it is not possible to diagnosticate the occurrence of suppuration and the presence of abscess more certainly than by the usual subjective and objective symptoms of pus-formation presented by the patient, which hitherto have had to be relied upon in arriving at an opinion as to the advisability of operation.

I beg to ask those in whose hands unquestionable cases of these ailments may come, whether abscess be suspected or not, that they will favor me with *fresh* specimens (about one pint) of urine, accompanied by a slip stating diagnosis (appendicitis, typhlitis, perityphlitis), and if it is believed an abscess is in process of formation or has formed. These specimens may be sent, in the janitor's care, to the Jefferson Hospital, Monday, Wednesday, Thursday, or Friday mornings by 10 o'clock, or, preferably, to my address, or they may be held to be called for at the house of the donor.

Very respectfully, D. D. Stewart, M.D.

2620 North Fifth Street.

REVIEWS.

Regional Anatomy in Its Relation to Medicine and Surgery. By George McClellan, M.D., Lecturer on Descriptive and Regional Anatomy at the Pennsylvania School of Anatomy; Professor of Anatomy at the Pennsylvania Academy of the Fine Arts, etc. In two volumes. Vol. I. Philadelphia: J. B. Lippincott Company, 1891.

The feature of this work that first attracts attention, and gives it a peculiar and distinctive value for the practitioner, is the illustrations. These are wonderfully faithful lithographic reproductions of photographs taken by the author from dissections made with his own hands, and they show not only his skill and ingenuity as an anatomist, but his judgment and dexterity as a photographer. Each object of interest in a plate is indicated by a numeral, placed not on the part itself, but at the side of the picture, and the two are connected by a horizontal line heavy enough to be readily descried, and yet so delicate as to cause no interference with the pictorial effect. The numbers are arranged in regular order, so that reference from the explanatory table to the plate, and *vice versa*, is rendered as easy as possible. To one that experiences annoyance at the disfigurement of illustrations by direct labelling, and at the expenditure of time in the search through a whole paragraph of reference-titles that are merely pitchforked together (and who has not been fretted by these things?), this simple device is a boon that should be highly appreciated.

The plates are all colored—the title-page tells us, "after Nature;" but, in the preface, the author admits the possibility of "some excess of tint or shade, as might be expected when the paints are mixed and applied with more enthusiasm than artistic skill." The coloring certainly enhances the worth of the pictures by as much as it facilitates the discrimination of their various parts; and nobody will be disposed to quarrel with any exaggeration of hue that he may observe. But, as regards most of the plates, we must take issue with the assertion that the tints are such as we find in the objects that they represent. It is true that arteries which have been injected with vermilion wax will permit the gorgeous pigment to show through their walls; but the color of these vessels then becomes artificial, and the imitation of it in the plate, however perfect, is not entitled to be called natural. The student deriving his knowledge of anatomy largely from pictures in which one set of vessels is always red, another always blue, and the nerves snow-white, unless he is wisely warned, is doomed to grievous disappointment when he essays operations upon patients in whom Nature has not considered his convenience by a similar distribution of pigments. And so, while we express our admiration of these superb illustrations, the very artificiality of which is a merit, we trust that we shall not be accused of cavilling, if we object to the statement that they are "colored after Nature."

Several plane sections are introduced with excellent effect, and we regret that this modern and peculiarly useful method of demonstrating the relations of the different parts in a given region has not been employed more extensively.

The number of figures in this volume exceeds one hundred, and a still larger series is promised for the second.

The text is excellent. The author is evidently a practical man, who understands the needs of the progressive physician and surgeon. This is evidenced by the conspicuous attention bestowed upon cranio-cerebral topography, a knowledge of the relations of surface-markings to underlying areas of the brain being demanded in these days of every surgeon. This involves the introduction of craniometric terms with which most medical men, and even some medical lexicographers, are unacquainted; but a familiarity with these words is, even now, essential to the comprehension of the reports of encephalic operations. When it is necessary, attention is directed to the practical bearings of the facts of particular structures, and the author imparts vitality to his discourse by emphasizing his points with brief and modest mention of cases coming under his own observation. The selection of illustrative instances is judicious, and the reader is not wearied by the presentation of many exceptions, so phenomenally rare as to be of no advantage to the great majority of practitioners. It was obviously intended to omit unimportant details, as is seen by the mere allusion to certain small venous sinuses at the base of the skull; but the difficulty of refraining from minute description is shown here and there, as in the case of the intrinsic muscles of the pinna of the ear, of which most of us are content to be ignorant.

It is not to be expected that so comprehensive a work

would be free from errors, and we have noted quite a number; but, while we do not care to make extended comment on them, we can hardly refrain from deprecating the slip by which the epithelial lining of the oropharynx is compared with that of "the rest of the mouth." It is so hard for some students to learn that the pharynx is not a portion of the mouth, that we deplore the sanction that is here afforded their mistaken notion.

The style of the writing is easy and for the most part clear; but occasionally there are infelicities of expression that cast some obscurity over the meaning. We suppose that it is of no avail to protest against the almost universal custom of anatomical writers that implies a perfect acquaintance with the original designs of the Creator, but the readiness with which the intention in the formation of the various organs is assigned is provocative of inquiry as to the source of their information.

It is gratifying to notice that the metric system is employed in stating measures and weights, and we experience a quickening of the long-deferred hope that the day is not distant when it will be unnecessary to translate each term of this easy—because decimal—system into the antiquated nomenclature in prevalent use.

This work approaches its subject with so different a purpose from that of the ordinary text-books on descriptive anatomy that it will not be expected to supplant them. Rather will it give them a new interest and value by complementing their service, and tending to render more attractive a branch of science that is too little studied both in and out of the schools, though it is at the foundation of all true knowledge in medicine. We congratulate the author upon his achievement in this first part, and shall look for the second with very pleasant anticipation.

A MANUAL OF VENEREAL DISEASES: BEING AN EPITOME OF THE MOST APPROVED TREATMENT. By EVERETT M. CULVER, A.M., M.D., Pathologist and Assistant Surgeon, Manhattan Hospital of New York City, etc., and JAMES R. HAYDEN, M.D., Chief of Clinic, Venereal Department of Vanderbilt Clinic, College of Physicians and Surgeons, New York. With Illustrations. 8vo, pp. 294. Philadelphia: Lea Bros. & Co., 1891.

THE arrangement of this book invites comparison. The work is divided into two parts. The first part, designated "Gonorrhea," is by Dr. Culver, and includes two chapters on chancroid. The second part, by Dr. Hayden, is devoted to a consideration of syphilis. It is with a sense of relief that one passes from the first to the second part, and one is refreshed by the transition. In the first part the essential facts are so often obscured by looseness of language, by indifference of style and diction, by lack of clearness of expression, that the reading becomes a task attended with fatigue and disappointment. The personal pronoun in the first person is so indiscriminately used in the plural or singular that one is at times in doubt as to the authority for the statements made. The wide range of subjects included in the second part is, on the other hand, treated with a conciseness, clearness, and completeness that command admiration and excite interest.

In no part of the work is a word said of synovitis—rheumatism, it is commonly called—as a complication of gonorrhea. This omission must be considered culpable, for the inflammation of the synovial membrane is sometimes followed by permanent impairment of the function of the joint. A little more stress, too, might have been laid upon the risk of fatal ascending pyelonephritis in the course of gonorrhea or of organic stricture of the urethra. We cannot agree with the dictum that directs the poulticing of a bubo as soon as its "character is made out by the rapid swelling and area of redness and the presence of a chancroidal sore;" nor have we a fear that if the bubo be "not thoroughly poulticed and have not well suppurated before opening" there will remain "much tissue in a half-necrotic state that must be scraped out with sharp spoons before packing." It is not an unnecessary caution to warn the operator of the danger of injury to the iliac vessels in the operative treatment of bubo, as well as the possibility of grave hemorrhage from ulceration.

The employment of glycerin, vaseline, or cosmoline as lubricants instead of olive oil, especially when rubber catheters are employed, is strongly recommended.

Operation is advised for stricture when the health of the patient is reduced, when cystitis exists, with retention of urine and loss of sleep; when there is renal disease, when time is an element of importance to the patient, and when the stricture is resilient. When the stricture is situated anteriorly to the triangular ligament, internal urethrotomy should be performed; when situated posteriorly, external urethrotomy.

The etiologic relation of syphilis and posterior spinal sclerosis is dubiously dismissed in a few words, despite accumulating evidence that tends to demonstrate the intimate connection between preëxisting syphilis and the subsequent development of the disease of the cord.

Surely the English language is rich enough in words to obviate the necessity for employing, in a work printed in English, only the French names for some of the syphilides.

PULMONARY CONSUMPTION: A NERVOUS DISEASE, CONSIDERED AS SUCH FROM A PRACTICAL, A CLINICAL, AND A THERAPEUTIC STANDPOINT. By THOMAS J. MAYS, M.D., Professor of Diseases of the Chest in the Philadelphia Polyclinic and College for Graduates in Medicine, etc. 12mo, pp. 185; paper. (Physicians' Leisure Library.) Detroit, Mich.: George S. Davis, 1891.

THE author says in his preface that "this essay is an effort to give a rational account of the principal causes and of the nature of pulmonary consumption, and has been written in the belief that no theory of the origin of disease can ever earn the right to permanent existence if it falls short in pointing out the path through which the disease may be prevented or alleviated." He rejects entirely the bacillus theory, and believes that the neurotic theory propounded in his pages explains most, if not all, of the varied and apparently opposing phenomena constantly observed in this disease, while it also serves the practical purposes of pointing out the means and methods of rational and successful treatment.

There is much logical argument, much unproved

speculation, much valuable compilation of statistics, much hyper-theoretical criticism to be found in these pages. The importance of hereditary influence, and especially of the physical conditions of the parents, independent of actual disease, is well set forth, and should be carefully studied by all intelligent physicians. The neurotic theory, however, seems to us too narrow. The nervous failure in consumptives is but part and parcel of the general nutritive failure, for which as yet we have no satisfactory term. Dr. Mays lays great stress upon rest in the treatment of consumption as a means of conserving the vital energies of the patient. He administers antipyretics to diminish waste of tissue consequent upon fever [a principle, but not a method, that we indorse], pays due attention to the digestive system, and gives most nourishing food. In addition, he administers cod-liver oil, hypophosphites, resorts to massage, galvanization of the pneumogastric, inhalation of oxygen, nitrous oxide, and compressed air, pulmonary gymnastics, and any other agent or agency that has power to enhance the local and general nutritive tone of the body.

NEWS ITEMS.

The Influenza Bacillus.—As we go to press the newspapers contain a cable report from Berlin that Dr. Peifer has discovered a bacillus deemed the specific cause of influenza. The microbe is said to be very minute, to resemble the micrococcus pyogenes, and to have been successfully isolated and used in inoculation experiments. It is scarcely necessary to add that such reports may be false in part or entirely.

Influenza a Contagious Disease.—According to telegraphic dispatches, the authorities of Dover, England, are attempting to cope with influenza by a rigorous application of the laws pertaining to the public health, which make it an offence for a person suffering with a contagious disease to visit public places. A number of persons who were suffering with that malady, and who had frequented public places, were charged with violation of the health law. They were convicted, and each of them was fined £5. It is believed to be the first instance, in England at least, of persons suffering from influenza being fined for endangering the public health by coming in contact with the general public.

Influenza in Horses.—It is said that an epidemic resembling influenza is causing ravages among horses at Normanton, England. In three coal mines twenty horses have died, and eighty are ill. Work has been stopped in the mines, and thousands of miners are idle.

Medical Legislation in Ohio.—At a recent meeting of representatives of the faculties of eight medical colleges of Ohio, a resolution was passed requesting the legislature to enact laws embodying:

1. The creation of a board or boards of medical examiners, in the composition of which equitable and just representation shall be accorded to the various recognized denominations of medical practice.

2. The examination of all candidates for the practice of medicine holding diplomas hereafter issued by medical colleges which shall be deemed in good standing by the board.

3. Exemptions from examination to extend only to those who at the time of the enactment of this law shall be recognized as legal practitioners within the meaning of existing statutes; but all legal practitioners shall be required to register.

4. A penal clause which shall secure the enforcement of the foregoing provisions.

The Berlin Academy of Science has appropriated twelve hundred dollars for the publication of scientific works. Three hundred and seventy-five dollars will be devoted to *The Law of Transformation of the Bones*, by Julius Wolff, of Berlin; five hundred dollars to *The Progress of Physics*, issued since 1847 by the Berlin Physical Society; and one hundred and eighty-seven dollars for the *Formulation of a Uniform Anatomical Nomenclature*, which for two years has been in preparation by the German Anatomical Society.

Prostitution and Syphilis.—It is proposed to hold in Paris, in 1893, an international congress composed of physicians, jurists, hygienists, economists, and sociologists, for the study of questions relating to prostitution and the propagation of syphilis.

An Army Medical Board will be in session in Chicago, Ill., during February, 1892, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before January 15, 1892, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate of a regular medical college, as evidence of which his diploma must be submitted to the Board. Further information regarding the examinations may be obtained by addressing the Surgeon-General of the U. S. Army, Washington, D. C.

Charles Meigs Wilson, M.D., third son of the late Dr Ellwood Wilson, died a short time ago at Knoxville, whither he had gone to occupy the chair of Gynecology and Diseases of Children in the University of Tennessee.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment, provided that the request for reprints be noted by the author at the top of the manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

INJURY TO THE SPINE: INVENTION AND APPLICATION OF PAPER JACKET.

BY J. MARSHALL HAWKES, M.D.,
OF NEW YORK CITY.

IN the early part of 1887, Ada G., aged twenty-three years, having received a fall, began to suffer from pain in the vicinity of the third lumbar vertebra. Later, the pain at times became so violent that she could neither stand nor sit, but was obliged to maintain the recumbent position. It did not, however, become continuous until the following autumn, when she became subject to such severe and prolonged attacks as incapacitated her for work.

The attendant physician ordered blisters to be placed transversely across the body of the affected vertebra. For nine weeks this style of treatment was continued, but little relief was obtained and the pain returned in all its severity on the resumption of work.

In May of that year, becoming convinced that she was not improving, she applied to a specialist in electro-therapeutics. For two months electricity was applied, but again the patient experienced but little relief, and the pain promptly returned on the resumption of work.

In December, ten months after the commencement of her trouble, I was called to see her. Since the ordinary, routine treatment had already been tried, nothing seemed to remain but to remove the superincumbent weight and thus, if possible, relieve the pressure upon the injured vertebra. Accordingly, the patient was suspended by the head and shoulders, when the pain immediately disappeared, but the patient as promptly fainted. It was found impossible to suspend her longer than a few minutes at a time, for several days, but as soon as she could remain suspended a sufficient length of time a plaster jacket was made. On its application the pain immediately ceased, but the patient constantly complained of the weight and the discomfort of the plaster jacket. Besides, after a few days, the disintegrating plaster began to sift down through her clothing, the odor of accumulating perspiration became very disagreeable, and the jacket itself grew loose and did not properly support the weight of the upper part of the body.

Finding it necessary, for the reasons stated, to supply something lighter, felt, leather, silicate of soda bandages, wood, nickelled electroplate, etc., were successively tried, but each had its serious and irremediable objections. Without entering into tiresome and useless details, they were all either hot, heavy, cumbersome, conspicuous, expensive, or difficult to prepare, etc. While in this quandary as to what to make, a paper shell, such as is used by professional oarsmen, furnished the needed suggestion. Surely, if paper could be used to make a pail, pan, car-wheel, or a boat, it certainly appeared to be an appropriate substitute for the materials in use for spinal supports. Accordingly, a mould of the patient's body was made by winding wet plaster bandages around the body, from the anterior superior spinous processes of the ilia to near the lower borders of the axillæ, while the patient was suspended, with the pelvis fixed. A plaster cast, made from the mould, was so modelled as to preserve the natural anatomical contour of the patient. Upon this cast, paper of various styles, weights, and qualities, cut into strips half an inch in width, were laid in successive layers, running in various directions, by means of glue, cement, shellac, and many other compounds, until, after a long series of very discouraging experiments, a jacket of pure jute fiber, free from clay and wood-pulp, was finally produced which the accompanying cut very excellently represents.

FIG. 1.

The ideal paper jacket.

This appliance was no sooner fitted to the patient than all her objections to the use of a spinal support vanished. It was neat, cleanly, thin, light, strong, inconspicuous, readily removable, and comfortable to the wearer. Only one thing more was necessary. It must be capable of expansion during respiration, and yet immediately contract and not lose its hold on the thorax during expiration. This requirement was met by dividing the jacket into two parts on the axillary lines, and lacing them together with an elastic lacing. This was done and the jacket seemed to meet every reasonable demand.

The patient was ordered to remove the jacket at night on retiring, and *not* to put it on in the morning till the spinal column had been thoroughly extended by suspension after the method already described. She was also given a thorough training in light gymnastics to strengthen *all* the other muscles of the body as well as those of the back. The result was very gratifying. She experienced immediate relief from the pain, and within two weeks returned to her work in a millinery establishment, where she has ever since remained. As her shape has changed somewhat from time to time, other jackets have been made for her with equally good results. Since then many other jackets have been made for other patients with lesions of a similar character, and always with the same success.

Compared with other orthopedic appliances intended to furnish a proper support for the spine when the lesion is in the lower dorsal or lumbar region, I believe that for the following reasons the method described is the best yet devised:

1. It is the thinnest, lightest, and strongest jacket, furnishing sufficient support, ever made. Though its average weight is only about twelve ounces, and its average thickness less than three thirty-seconds of an inch, yet it is able to sustain a weight of over two hundred pounds.

2. It is impervious to moisture; hence, does not absorb perspiration, and consequently does not become unbearable to the wearer.

3. A lady can wear it in place of the ordinary corset without "letting out" her dresses or making any changes in her ordinary wearing apparel.

4. The most muscular laborer engaged in the severest kind of manual labor finds it capable of sustaining any necessary strain.

5. It furnishes a more convenient, efficient, and durable support for the jury-mast, shoulder-brace, abdominal supporter, truss, leg-brace, etc., than any other kindred appliance.

6. It does not disintegrate and soil the clothing like plaster, or rust out like "alloy wire," or soften like felt.

7. It affords a solid base from which to furnish direct pressure to remedy any existing or developing deformity, yet accommodates itself to the action of the muscles of respiration.

8. It can be easily modelled to fit any exaggeration of anatomical contour, and can be ventilated by means of eyelets to any extent.

9. It is practically indestructible. The patient can never wear it out.

10. Its cost is no more than that of any other first-class appliance.

Soon after perfecting the paper jacket, I extended the application of paper to the making of splints. The result was as gratifying as in the case of the jacket.

The preparation and use are best illustrated by the following case:

On September 9, 1891, Carl W., nine years of age, while playing in the street, was run over by a heavy wagon and sustained a double compound comminuted fracture of the right leg. I saw the patient within a few minutes after the accident. No important vessels or nerves were injured, and after the usual antiseptic dressing had been applied, the leg was put up in a Levis splint (nickelled electroplate). In four days, the swelling having subsided, a plaster bandage was applied, immobilizing both knee and ankle, but leaving a fenestra over the seat of the injury.

Several difficulties immediately presented themselves: the joints could not be immobilized for an indefinite time without fear of ankylosis; the plaster bandage could not be removed to make passive motion of the joints without great trouble and danger of displacement of the bones; the limb could not be bathed and the accumulating scales of epidermis removed, for a similar reason; the wound could not be re-dressed without the disintegrating plaster falling into it, unless much precaution was used.

Fig. 2.

The ideal paper splint.

Indeed, the annoyance became so great that I decided to make a splint of paper on the same general plan as had been used in the construction of the paper jacket. Accordingly, a shallow box, with adjustable sides and ends, was made ready, and filled half-full of prepared plaster. Into this plaster the limb—nude, shaved, oiled, and thoroughly extended—was lowered, until the plaster covered the lower or posterior half of the limb. As soon as the plaster set, a brush filled with melted paraffin was passed over it. Over this enough plaster was poured to cover the limb. As soon as the plaster had set, the sides and ends of the box were let down, the

upper half of the mould was removed, and the leg was carefully lifted out of the lower half. The whole time occupied was less than fifteen minutes. The upper half of the mould was returned to its place, the box restored, and a perfect mould of the limb was thus made ready. A cast made from the mould was used as a model on which to lay the paper for the splint. The accompanying cut represents the splint after it had been cut from the cast and bound. Hooks were inserted in both sides of the splint.

As soon as this splint was adjusted to the limb, the disadvantages of plaster were more readily apparent. After using it for ten weeks in one of the worst fractures that I have ever seen, the following points of superiority were demonstrated:

1. Since it is made on a plaster cast of the limb itself, it must fit perfectly.

2. Since the cast was made while the limb was fully extended, it follows that this position of extension will be maintained as long as the splint is carefully adjusted.

3. Since it weighs less than a pound, is only three thirty-seconds of an inch thick, and yet is able to sustain a weight of over two hundred pounds, it follows that it is the lightest, thinnest, and yet the strongest splint ever made.

4. Perfect immobilization of a joint can be secured, yet the joint can be inspected at a moment's notice, since either the anterior or the posterior half can be removed without disturbing the other, and because either half of the splint is able to keep the limb in its proper position, for a limited time, without the aid of the other.

5. Both the outer and the inner surfaces are waterproof; hence there is no absorption of perspiration, no odor, no fear of getting the splint wet while bathing or dressing the limb.

6. It offers no obstacle to making passive motion of the joints at any time, since by removal of the posterior half the knee can be flexed or the foot extended at will without fear of displacement.

7. In compound fractures it simply becomes necessary to remove that half of the splint which covers the wound, and irrigate and dress it, with the confident assurance that the other half will hold the limb securely.

8. During the period of convalescence the patient can wear his usual clothing over the splint.

9. The uniform pressure checks muscular spasm and lessens the tendency to swelling and edema.

10. There is no great difficulty to be overcome in the preparation of these splints, and any first-class instrument-maker should be able to furnish them with facility.

NEUROMA.[1]

(With Report of a Case.)

By EDMUND J. A. ROGERS, M.D.,
PROFESSOR OF CLINICAL SURGERY, UNIVERSITY OF DENVER; SURGEON TO THE ARAPAHOE COUNTY HOSPITAL, ST. LUKE'S HOSPITAL, ETC.

WHEN, in connection with the rarity of nerve-tumors, we consider the complex structure of nerve-tissue, we can easily understand the confusion that exists in the nomenclature and classification of these tumors, and their generally undetermined pathological structure. Thus, in an ordinary nerve-trunk we have the nerve-fibers proper surrounded by their medullary coats of myelin, this limited by the neurilemma, set in the endoneurium, and this again surrounded by the laminated perineurium, and all included in the coarser connective tissue of the epineurium. Each differs in its structure, and each is liable to the pathological changes to which all tissues are subject, each is liable to its own peculiar changes, and any two or all of them are liable to be attacked at the same time. Add to all this the difficulty of demonstrating axis-cylinders and other nerve-structures satisfactorily by ordinary histological methods, and what wonder that we seldom find two nerve-tumors described as being similar in structure?

The confusion begins in the very title. The clinical surgeon has few means during the life of a nerve-tumor to diagnosticate its structure, whether of fibrous tissue, or of pure nerve-tissue only, or mixed. He has therefore, of necessity, come to classify all tumors connected with and inseparable from nerves as neuromata.

On the other hand, pathologists, and especially the German pathologists, insist that it is highly improper to call a tumor a neuroma that has no true nerve-tissue in it.

We must, however, give some name to these tumors before they get into the pathologist's hands, and in the absence of a better we shall, therefore, adhere to the old definition that all tumors connected with and inseparable from the nervous system are neuromata. But when we come to a true scientific classification we find these growths divided into two great classes, not always distinct from each other, true neuromata and false or spurious neuromata. In the former the characteristic and predominating tissue is nerve-tissue, while in the atter the nerve-elements are absent, or occupy only an accidental or subordinate place. All neuromata are rare, but true neuromata are found much more seldom than the spurious.

True neuromata may be divided into three classes:

---

[1] Read before the Colorado State Medical Society, June, 1891

1. The ganglionic, medullary, or cellular neuromata.

2. The fasciculated or fibrillar neuromata, and—

3. The plexiform neuromata.

The ganglionic are found almost entirely in the nerve-centers, and are made up chiefly of ganglion-cells and naked axis-cylinders. They are rare, and are not of surgical importance.

The second variety, however, is of more interest. Its characteristic tissue is constituted of ordinary nerve-fibers set in connective tissue, the arrangement of the two varying greatly in the different specimens. As long as the connective tissue does not too greatly predominate and is related to the nerve-elements as its matrix, the growth is still called a true neuroma. There are said to be some tumors in this class, although they are very exceptional, in which the constituent nerve-fibers are non-medullated. Such tumors are consequently termed amyelinic, to distinguish them from the myelinic neuromata, or those having medullated fibers.

The usual seat of neuromata is in the course of the spinal nerves, principally in the extremities, but they are sometimes found on the cranial, and very rarely on the sympathetic nerves. The growths usually appear as simple spindle-shaped or oval enlargements of the nerve, are usually symmetrical in shape, sometimes flattened, and of any size up to or even larger than a hen's egg. They are said to be generally grayish in color, and firm and elastic to the touch. They seem to be produced by a local hyperplasia leading to an hypertrophy of the nerve-structures, and can often be traced to an irritation or injury to the nerve. This injury is sometimes subcutaneous. That the lesion may first cause simple inflammatory changes, and these lead to hypertrophic changes, there can be no doubt. It is said that neuromata do not always invade the entire nerve-trunk, but that they may grow upon only a section of it, crowding the remainder to one side. To this class belong the terminal, traumatic, or amputation neuromata found in stumps. These tumors are said to be usually connected to the cicatrix by small radicles. They are generally small in size, and only exceptionally cause any inconvenience.

We find placed in this class those tumors that develop in the peculiar constitutional condition that is characterized by the formation of a great number of nerve-growths, although they may be more properly fibro-neuromata. These multiple neuromata sometimes develop in immense numbers—in one case estimated at over two thousand. They sometimes appear only on one nerve, sometimes on a single set of nerves, and sometimes throughout the entire nervous system. This condition occurs almost exclusively in males, and may perhaps be due to some hereditary neurotic taint. It is not infrequently seen in cretins, and a few cases have been encountered in idiots.

The third variety mentioned—plexiform neuromata—includes those rare congenital growths made up of varicose-like convolutions of hypertrophied nerve-cords. They are so rare as yet to have no clear distinctive description, and are often confused with other similar tumors. They may lie deeply, or be immediately beneath the skin. They most frequently occur on the branches of the fifth nerve, but have been found in various other locations.

Nerves are liable to all the pathological changes that occur in other tissues, and these localized changes constitute the usual cause of the simpler false neuromata. Of these by far the most common is the fibroma. This may origininate in any of the fibrous tissues of the nerve, and may grow to a considerable size without affecting the nerve-tissue proper. Thus, if in the epineurium or laminated perineurium, it may grow only on one side of the nerve as a pedunculated or semi-detached growth, or it may completely encircle the nerve, forming a cylindrical sheath, which may be easily dissected away. If it arises in the interior connective tissue it may crowd the nerve to one side, which will then pass in a sort of groove in the tumor; or, if still more central, it may divide the nerve into several fasciculi that may become widely separated, but may still remain distinct and easily separable from the fibroma. These growths are generally harmless, and seldom interfere with the functions of the nerve. Clinically, they closely simulate the fibrillar neuromata, but are apt to be more globular and not so spindle-shaped as the true neuromata; they may be more laterally attached to the nerve, and hence more movable.

The fibromata, again, are clinically closely simulated by the myxomata, which are said to be the next most frequent in occurrence of the non-malignant spurious neuromata. Nerve-cysts are also occasionally found, as are also such mixed tumors as cysto-myxomata, fibro-myxomata, lipomatous myxomata, etc. Spurious neuromata may also be due to malignant diseases of the nerve. Of these, sarcomatous growths are the most common, while primary carcinomatous tumors are very rare indeed. Gummata are rare in nerves, except in the cranial nerves. In leprosy a peculiar true neuroma is often found present, and may play some part in the pathology of the disease.

Closely connected with neuromata, but not properly belonging to them, are the painful subcutaneous tubercles—the neuromata dolorosa of Virchow—of which much has been written. These are little nodular bodies, the seat, or rather the center, of excruciating intermittent and remittent pain and tenderness. A drawing sensation, not definitely

localized, is also sometimes experienced about them. They vary in structure, being sometimes described as simple fibromata, sometimes like true neuromata, but they are generally much more complex. They are not always found to be connected with the nervous system, but, of course, are probably so connected. It seems reasonable to suspect that they are altered or hypertrophied superficial nerve-endings, although this has not yet been demonstrated. They occur most frequently on the arms, back, and neck, but may occur at any part of the body. They are much more frequently found in women than in men. Where not too numerous, treatment by simple extirpation is satisfactory.

Neuromata in general have no characteristic symptoms. When situated on a large nerve-trunk there are generally more or less defined neuralgic pains, sometimes terribly severe in intensity, intermittent and remittent in occurrence, and seemingly affected by external and constitutional circumstances, as in true neuralgia, or there may be only a deep, dull aching. Later on, sensory symptoms, such as formication, tingling, and numbness, and such motor affections as twitchings, tremors, and weakness may develop. Actual sensory and motor paralysis, if seen at all, usually are late in appearance. Indeed, one is surprised to find how few and how slight the symptoms are, and the symptoms do not seem directly to depend upon the size of the tumor.

In heterologous growths, when the nerve is invaded and destroyed, we, of course, expect to find more rapid growth and greater loss of function in the parts than are found in simple growths. When a tumor develops in a bony canal, we expect paralysis below from pressure. Occasionally, reflex symptoms are encountered, such as pain and muscular contractions. Even epileptiform convulsions have been stopped by the removal of a superficial neuroma. When the symptoms are marked, weakness is generally noticed in the muscles supplied by closely associated nerves.

Neuromata cannot be diagnosticated from symptoms alone. When the growths are superficially situated they are sometimes found to be tender, and manipulation may cause pain in the distal course of the nerve. But even these features are remittent. In idiopathic neuromata the tumor may vary in size from time to time, and may even disappear. We are assisted in diagnosis by finding that the tumor is in the course of a nerve, and that it is freely movable to one side of the nerve, but fixed in the other direction. Pain and tenderness in the tumor, and in the nerve beyond, can generally be abolished by pressure on the nerve above the tumor. Non-traumatic, non-malignant neuromata are very slow in development, but they may occur at any age, and may grow to any size. Virchow states that they are found more frequently in the tuberculous and scrofulous diatheses. They are benign, but true neuromata have a tendency to recur after removal.

When treatment is demanded, extirpation is alone of benefit, but should not be lightly undertaken. In case of multiple neuromata it is unwise to attempt removal, and this should be undertaken only when some one local tumor is causing great and persistent distress. In these multiple growths the prognosis is generally good, as they appear seldom to directly affect the duration of life.

The case that I present herewith is one of much interest:

Miss Jennie S., unmarried, twenty-three years of age; is a native of Sweden, but came to Kansas twelve years ago. In childhood she had attacks of quinsy, and when first in Kansas had malaria severely. She gives no history of any other disease, and I can discover no tuberculous or scrofulous taint, and no specific history. She was well and hearty, when in May, 1889, she struck her arm on the sharp corner of an ice-chest. She scraped the skin, and suffered a severe bruise over the inner side of the lower portion of the arm. The part was sore for about a week, when all symptoms disappeared for about two months. The girl then began to have shooting pains from the seat of the injury down into the little finger and hand. Swelling or other symptoms were not observed. In the following fall, as the pains were growing worse, she placed herself under medical treatment. During the winter, the pains and "queer" sensations in the arm and hand progressively increased, and at night became so severe as to prevent sleep. In the spring of 1890, while on her way to Denver, she noticed the arm swelling about the site of the bruise; the pains became intense, and soon the hand also swelled. The swelling in the arm was said to be an abscess, and was poulticed, but was never opened. The swelling gradually subsided, but the little finger remained blue, weak, painless, without feeling, and seemed in the way. As the swelling left the arm, a small lump remained. Soon the pain began to return, and became very severe at night, the tumor gradually increasing in size. As it did so, the hand got weaker and more awkward; it was numb and tingling, and there was no feeling on the inner side, so that the girl was constantly burning and hurting it unconsciously. She says that she noticed wasting of the inner side of the hand, the ball of the thumb, and between the bones of the hand. This grew worse gradually, the hand becoming very awkward and in her way. On February 5, 1891, she called upon Dr. Eskridge, who examined her and made the following notes of her condition, which he has kindly allowed me to use here:

"Sense of touch was completely lost in the little finger of the left hand, and in the corresponding portion of the hand to the wrist-joint. Tactile sense was present on the ring finger on both the

inner and outer surfaces. Tactile sense normal over the arm and forearm. Pain-sense affected only in the little finger, where it was simply lessened, not abolished. Temperature-sense in the same region lessened. The little finger could neither be flexed nor extended. It remained in a semi-flexed position, on account of rather firm contractions of the flexor muscles. It was impossible for her to abduct or adduct the little finger. The grasp of the left hand was very weak, and the whole hand was moved slowly and awkwardly. Only the muscles of the little finger were tested by electricity, and these were found partially degenerated."

Dr. Eskridge subsequently advised her to go to the County Hospital, which she did, and was there placed under my care.

I first passed an exploratory aspirating-needle into the tumor, as there seemed to be obscure fluctuation in it, but the only result was to cause intense pain—the old pain, she said—down into the little finger.

On February 24th we operated by cutting down longitudinally over the tumor, which was found to be a symmetrical spindle-shaped enlargement of the ulnar nerve, its center being about three inches above the elbow. The tumor itself was about two and a quarter inches long and two inches in circumference, but the entire nerve, as far as it was exposed in both directions, was found much hypertrophied and hardened. No line of demarcation between the nerve and tumor could be found, the latter being to all appearances simply an enlargement of the former. After dissecting the tumor perfectly free on all sides it was incised longitudinally, and gradually split quite in two. Within a definite capsule a grayish-white substance was found, growing softer toward the center, and closely resembling the white substance of the brain. In the center was a cavity filled with a thick, gray, grumous substance, probably desiccated pus. The matter appeared homogeneous throughout. The nerve was then divided just above the tumor, and the tumor drawn up so as to stretch the lower portion of the nerve as much as possible. The nerve was then divided just below the tumor, and the extremities still not approximating, the upper portion was grasped by the fingers and drawn down forcibly as far as possible. Although two and a half inches of the nerve had been removed, the extremities were then brought to within three-eighths of an inch of each other by means of two strong catgut sutures passing completely through each nerve-extremity at right angles to each other. The wound was then closed entirely, and the arm from the shoulder to the knuckles placed on a straight splint. The patient was kept in bed. On the second day it was found that some sensation had returned in a small area on the little finger, and that there was some power of motion in the finger. The wound healed by first intention, pain disappeared entirely at once, and though the hand was swollen for some time, improvement soon set in and has ever since continued. The straight splint was kept on for about five weeks, but the hand was not allowed to be put to any use for seven weeks. It was then treated by massage. By rapid and constant improvement, strength and sensation almost completely returned.

At the present time the hand appears normal, except that the muscles of the third and fourth intermetacarpal spaces seem still wasted. The grip is strong, and the hand seems as useful as it ever was.

I here give the report made by Dr. Lobingier, the pathologist of the hospital, to whom the tumor was submitted for examination :

"The tumor belongs to the class of fibrillary myelitic neuroma, and consists of collections of nerve-fibers bound together by connective tissue, running in some instances directly and in other places tortuously through the tumor. Consequently some of the nerve-fasciculi fall directly in cross-section, whereas others appear wavy and parallel, or branched, being cut longitudinally. Certain sections show a preponderance of fibrous tissue, richly studded with leucocytes. One area, which appears in almost every section, is remarkable, in that the nerve-bundles are in various stages of waxy degeneration, and this, in cross-section, appears dense and homogeneous. Owing to the fact that the tumor was hardened before it came into the demonstrator's hands, it was impossible to stain the axis-cylinders, as could have been done in the fresh specimen with gold chloride. The medullary sheath and white substance of Schwann may be made out in the cross-sections of the fasciculi. The neoplasm is remarkable for its excessive vascularity, and the waxy degeneration of certain nerve-studded areas, an unusual phenomenon."

What the ultimate outcome of this interesting and perhaps unique case will be remains to be seen. As we have said, these tumors tend to recur. In this case a much-thickened and greatly-stretched nerve was sutured, leaving a considerable interval. These conditions, I fear, give ground for apprehension.

I have little doubt that the blow two years ago set up a traumatic neuritis, which resulted in the extensive thickening, and later in a local intra-neural suppuration. This became quiescent after so permanently damaging the nerve as to make its functions hopeless without surgical interference.

MECHANICAL INFLUENCES IN PELVIC DISORDERS.[1]

By KATE REYNOLDS LOBINGIER, M.D.,
of Denver, Colorado.

It is written that "man is fearfully and wonderfully made." Must we confess that woman is fearfully ill-made? Have all mechanical and physical laws been disregarded in her construction, so that pelvic disease is a necessary sequence? There are vigorous women that have the strength and endurance of men. If the constructive idea is at fault, why should the uterus of one woman be well sustained, and that of another sink like lead? We

[1] Read before the Colorado State Medical Society, June, 1891.

have here a problem in physics. If we would solve it, we must do so by the general principles of mechanics. If we accept this truth, we shall be willing to search patiently for natural principles of support, but, if we regard pelvic disease as inevitable, we shall be satisfied with palliative measures.

Pelvic disorders may be grossly classified as displacements and inflammations. In discussing mechanical aids we shall have most to say in reference to malpositions, but it is understood that whatever restores normal position helps the pelvic circulation, thus removing the cause of inflammation and acting as a direct curative agent.

In considering aids for the correction of pelvic deformities, it is common to regard the pessary of paramount importance. No discussion of the subject would be comprehensive that failed to consider this popular instrument.

It is easy to multiply objections against the pessary, but one most rarely insisted upon is the use of this instrument to the neglect of fundamental physiological laws.

Among other objections to the pessary are the following. In many cases the instrument cannot be tolerated, in others it is useless, and there are cases in which it does actual harm:

1. When chronic peritonitis exists, or a prolapsed ovary is present, the pressure of a foreign body is too painful to be endured.

2. If a pessary is not carefully selected and properly adjusted, so as to receive support from the bony frame-work, it will lie idle and useless in the vagina.

3. An effective pessary will in time cause distention and lessened tissue-tone. The vaginal wall will lose elasticity, and become flaccid, without retaining-power.

4. In time the patient becomes enslaved to the use of the pessary, and this fact must be considered when it is remembered that, sooner or later, there will come an end to the utility of the instrument.

5. Sometimes a foreign body, like the pessary, acts as a constant source of irritation. The catarrhal discharge that results, and the retention of this septic material, may cause softening of the tissues and actual imbedding of the instrument.

6. Skilfulness and care will overcome many objections to the pessary, but the fact must always remain that it is a bad mechanical principle to support a body like the uterus by a prop from below. If the uterus were enclosed in a bony cavity and shut off from all connection with other organs, a small instrument like the pessary might be sufficient; but remember that we have an immense weight of superimposed viscera bearing down from above, and the pessary must perform a task akin to that of Atlas with the earth upon his shoulders.

To support the earth with a prop is an ancient and crude idea. It took years for the truth to develop that the sustaining force is far distant in the sun. The analogy is good. The main sustaining force of the uterus is not located in the pelvis, but acts from a distance.

Is it expedient to rule the pessary out of practice because objections may be urged against it, and because the instrument is capable of misuse? In answer to those that reject pessaries, Thomas says: "Pray, then, what *do* you use?" It is well to remember that an elaborate nihilism is often as disastrous as the too ardent advocacy of a questionable measure. It must be admitted that a certain benefit accrues from the temporary employment of the pessary as an adjunct to other and more rational methods of treatment. When great congestion exists, the elevation of the uterus by means of a well-adjusted pessary allows the blood-current to resume its normal course, the size and weight of the organ is reduced, and the pessary acts substantially as a curative agent. The instrument may also prove a valuable palliative measure by relieving tension on the nerves and the attending suffering.

The influence on the patient's mind must also be considered. It is often true that the introduction of a pessary is followed by instantaneous relief. The patient is greatly encouraged, and may be induced to lead a more active open-air life. The benefit to her general health thus derived may be a valuable element in establishing a permanent cure. The facility with which temporary relief may be given and the ease with which the pessary may be applied make this instrument popular both with physician and patient. The effort necessary to gain proper coöperation on the part of the patient in securing adequate support to the uterus by other and more permanent means makes resort to this instrument a natural compromise. Many of the arguments adduced against the use of internal supports apply with equal force to external support by means of the abdominal bandage. Both are palliative and temporary, and this is especially true of the external support. It would be idle to argue that an abdominal bandage is in any sense curative, but the lifting up of the viscera relieves the dragging sensation that is often the source of much discomfort. It is not uncommon for women to assume the responsibility of wearing such a supporter without the advice of a physician, and with no other assurance of its propriety than the temporary comfort afforded in walking and standing. A patient may become so wedded to this means of relief that she is afraid to step on the ground without such aid, and it is true that the longer she wears the bandage the weaker do her muscles become. The application of a splint to the brachial region will cause atrophy and

incompetency of the biceps, and the continued use of the external support is in its effect on the abdominal muscles just as pernicious. The evil results of the bandage are most strikingly seen in puerperal women. The uterus is large, the ligaments yielding, and the bandage tight. The patient believes her form is being preserved in the best possible manner, but what is really the result? The uterus moves in the direction of least resistance, and the fundus finds a resting-place in the hollow of the sacrum; retroflexion, subinvolution, and metritis are likely to be the unfortunate sequelæ. This serves to illustrate what the tendency may be in a non-puerperal patient, if there is great congestion of the uterus and laxity of the tissues.

A mechanical agency more effective than the best supporter is *gravity*. This force is resistless, and most of the physical ills of womankind have been ascribed to its pernicious influence. A factor thus potent in the production of pathological conditions must be equally powerful in affording a remedy when the conditions are reversed. Water rises in an artesian well, forced up by the gravity of water in the adjacent hills. A loaded car is drawn up the steepest mountain-side by the weight of a descending car. Why may not the force that caused prolapse be made the effective agent to restore correct position?

As an illustration of the excellent results obtained from gravity, we may instance the retroflexed, pregnant uterus. Skilful manipulations from below may prove entirely futile in rectifying this condition. But if the patient, resting on her elbows, is by a nurse lifted to an angle of forty-five degrees, the uterus will fall forward. If this exercise is repeated every day till the fundus has risen above the promontory of the sacrum, a complete cure is effected, and the distressing effects of incarceration are avoided. A remedial agent is sometimes effective in proportion to its simplicity.

In cases in which the pelvic organs are congested and misplaced, it is remarkable what excellent results may be obtained by the persistent use of the knee-elbow and similar positions. The blood-current at once becomes more active, the nerves are relieved of tension, and pressure on neighboring structures is removed. Reclining with the hips elevated, lying in the Sims position, or on the face, are palliative measures of great value.

The tendency of gravity is to remove the causes of disease, but, at best, it can be only an intermittent force. Nature's method of sustaining should act continuously.

The *suction-force of respiration* is a power that is constantly operative, and it is entirely competent to regulate the movements of a refractory uterus. With the aid of a Sims speculum, under favorable conditions, a to-and-fro movement of the uterus may be observed. If the waist is constricted, or the breathing feeble, this motion is slight or absent. But if the respirations are vigorous, it will be noticed that at every expiration the cervix is drawn up out of sight. This "breathing" of the uterus is necessary to pelvic health.

The human trunk is substantially constructed on the model of a suction-pump. We may consider the chest, abdominal, and pelvic cavities as one continuous tube. In this cylinder the diaphragm moves up and down after the manner of a piston. In a pump some thirty feet of water is lifted. A force that has this power ought certainly to lift the viscera upward for several inches. Suction-force is the power that Nature has provided for the support of the pelvic contents.

The organization of a woman is not structurally defective, but the adjustment of parts is peculiarly delicate, and any interference with normal action is followed by disease.

Over-exertion has been assigned as a cause of uterine disorders, but as a matter of fact we find that women of sedentary lives suffer more frequently than those that lead lives of normal muscular activity. A seamstress is more apt to be afflicted with pelvic disease than a housemaid. Any exercise that keeps the blood in active motion must have a derivative influence on the pelvic viscera; but exercise of the upper extremities is most directly beneficial in the prevention and cure of uterine disease. The close connection between the arms and pelvis is evident. In the simple exercise of standing with the hands clasped behind the head, the chest-walls are lifted outward and upward by the action of the great pectoral muscles attached to the humerus, as a result of which the chest capacity is augmented, the diaphragm rises, the abdominal contents have room to ascend, and those of the pelvis follow.

Sylvester's method of artificial respiration illustrates the extreme value of arm-movements in cases of feeble breathing. This exercise is itself an admirable one for its effect on the pelvic contents.

But it is clear that any exercise intended to develop respiratory power must utterly fail if there exists an antagonistic force capable of nullifying every effort. The corset has been cordially condemned for its restrictive influence on respiration, but, in addition, many women wear tight bands equal to five yards of continuous bandage. Attached to these bands there are often from six to seven pounds of heavy clothing, exerting direct pressure downward.

Suppose we have a suction-pump in which the cylinder is somewhat yielding. Around the middle, were the piston works, let us put on stiff splints and bind them fast with five yards of continuous band-

age, then suspend from the bandage seven bags of shot that weigh each a pound. Now try to move the piston. The excursions are of small amplitude, but the wonder is that the piston moves at all. Nature meant the uterus to be sustained, but she made no allowance for Parisian fashions. The lifting upward of the viscera implies that there must be space enough below the diaphragm for the abdominal contents to pass freely upward. Any mechanism whereby this space is limited must in a double sense prove injurious. Not only is free movement of the respiratory area prevented, but the abdominal viscera are held down by hydrostatic pressure on the pelvic organs. Abdominal respiration in women must be restored before we can successfully combat the many forms of uterine disease.

The argument presented for discussion is briefly as follows:

1. Mechanical remedies are important, and local applications are not sufficient.

2. The four mechanical aids considered are the *pessary*, *abdominal bandage*, *gravity*, and the *suction-force of respiration*. Of these, the first two are least effective, because they operate on incorrect mechanical principles. Their aid is temporary and palliative, and their continued employment subject to abuse.

3. *Gravity* is a powerful palliative agency, and its tendency is curative, but it is a force that cannot be employed continuously, and it is directly dependent on the patient's will.

4. The only mechanical power that can be in constant operation, and is strictly curative in uterine disorders, is the *suction-force* of unrestrained respiration. This power is fundamentally correct in principle, it operates independently of the patient's will, and is the only force adequate to successfully antagonize the prolapsing tendency of gravity.

5. Any mechanical treatment must fail of complete success if it ignores the upward respiratory lift of the viscera, dependent on unrestricted action of the diaphragm.

A CASE OF BILATERAL LUMBAR ABSCESS ASSOCIATED WITH POTT'S DISEASE.[1]

BY J. K. YOUNG, M.D.,
OF PHILADELPHIA.

THE following case illustrates the result of conservative treatment of a very severe bilateral lumbar abscess accompanying Pott's disease in a young child.

J. P. B., a male child, four years of age, referred to me January 28, 1890, by Dr. William E. Hughes, had been in perfect health until the previous summer, when he fell down a step, striking against a stove. The mother subsequently noticed a small projection in the lumbar region, and the child complained of pain in the knee. Examination revealed caries of the spine, with a projection of the spinous processes of the eleventh and twelfth dorsal and the first lumbar vertebræ. A Taylor spinal assistant was applied and worn, and internal and local remedies were employed. Subsequently a very large abscess developed on the left side; this was twice aspirated, and still later a smaller abscess developed on the right side, and was allowed to open spontaneously. Full antiseptic dressings were employed throughout, and at present there is a very small superficial sinus unhealed. The vertebræ are ankylosed, and the child now enjoys good health, and runs and plays as other children.

The subject of lumbar and iliac abscesses has already been so ably discussed that in presenting the present case of recovery from severe bilateral abscess it will only be necessary to refer to the seat of the disease and the importance of the fasciæ in determining the course, exit, and prognosis of purulent collections in the lumbar region. It is a well-recognized fact that abscesses in every region of the spine follow a pretty definite course and termination, the direction and exit of the pus being influenced by the seat of the lesion and by the fasciæ and aponeuroses. Thus, in the cervical region, the deep cervical fascia plays a most important part in determining whether the abscess shall take an anterior course and open into the posterior wall of the pharynx; whether it shall burrow beneath the deep fascia into the thorax as a mediastinal abscess, to terminate by breaking into the trachea, esophagus, or through an intercostal space; or whether it will pass laterally between the longus colli and scaleni muscles, and will thus open posteriorly to the sterno-mastoid upon the side of the neck.

Treves, Jacobson, Hilton, and others have called especial attention to the great importance that, from a surgical point of view, attaches to the complex arrangement of the cervical fascia and Koenig, Henke, Saltman, and others have pointed out the importance of the fasciæ generally in determining the direction and pointing of abscesses from whatever cause. In the dorsal region, the strong fasciæ binding the ribs together determine whether the pus shall find its exit posteriorly upon the skin of the back or sides, a short distance from the spine, or whether it shall pass beneath the ligamentum arcuatum internum, and enter the psoas sheath to terminate in Scarpa's triangle beneath Poupart's ligament. In the lumbar region it does not appear to me that sufficient attention has been given to the importance of the fasciæ in determining the course of lumbar abscesses from caries of the vertebræ and

[1] Read before the American Orthopedic Association at Washington, September, 1891.

the effect of this change of course upon the prognosis of these cases.

The usual course for abscesses in the lumbar region is in one of four ways:

First, to be directed to the iliac region along the aorta and external iliac arteries, to terminate as a gluteal abscess; second, to enter the psoas sheath and become a psoas abscess; third, to burrow through the fasciæ of the quadratus lumborum and the internal oblique muscle, to appear on the surface between the external oblique and latissimus dorsi at the outer border of the erector spinæ muscles; or, fourth, to gravitate beneath the internal iliac muscles over the posterior brim of the pelvis, perforating the great sacro-sciatic foramen, to appear as a gluteal abscess. (See table.)

The variations of the course and termination of a lumbar abscess depend, first, upon the seat of the lesion, and second, upon the attachment of the fasciæ. In caries of the spine it is a well-recognized fact that the tuberculous process is usually limited to the bodies of the vertebræ, the articular and spinous processes never being primarily affected, and but rarely secondarily involved, their compact structure apparently protecting them. In exceptional instances the lesion is superficial and limited, the intervertebral cartilages escaping, but as a rule extension occurs by contiguity of structure until a considerable number, even all, of the vertebræ may become involved.

In examining a sectional diagram of the lumbar region it will be observed that the sheath of the psoas muscle and the lumbar fascia are the most important structures in this connection. The sheath of the psoas is a thin fibrous membrane derived from the iliac fascia—attached above to the ligamentum arcuatum, laterally by a series of arched processes to the intervertebral substances and prominent margins of the bodies of the vertebræ, and continuous below with the iliac fascia. The lumbar fascia divides into three layers, inclosing the quadratus lumborum, multifidus spinæ, and erector spinæ muscles, and giving attachment to the internal oblique. Its anterior and middle layers are attached to the transverse processes, and its posterior layer to the spinous processes. Above, its anterior layer is attached to the lower border of the last rib, forming the ligamentum externum. The posterior surface of the psoas muscle is separated from the quadratus lumborum by the anterior layer of the lumbar fascia—a very thin fascia—but the greater part of the muscle is firmly supported behind by the erector spinæ muscles. In front, the quadratus lumborum is very thin, and offers but little resistance to the exit of the pus. If the abscess find exit upon the surface of the vertebræ anteriorly to the attachment of the psoas fascia, it will terminate by burrowing along the great vessels, or become an iliac abscess; if it open posteriorly to the psoas sheath it will burrow backward and laterally along the middle layer of the lumbar fascia, separating the quadratus lumborum from the internal oblique, through the internal oblique, and between the external oblique and latissimus dorsi, to appear at the outer border of the erector spinæ muscles.

This was the course of the abscesses in the case reported. The sheath of the psoas and the lumbar fascia, as thin as they are, are nevertheless very important factors in determining the direction, and with the direction, the prognosis of lumbar abscesses. So important do these fasciæ appear to the writer, that he would suggest a division of lumbar abscesses into two classes, external and internal, their relation to the sheath of the psoas fascia and the anterior layers of the lumber fascia determining their position.

Variety.	Course.	Exit.
Cervical	*a.* Anterior.	Into posterior wall of pharynx.
	b. Burrow beneath deep fascia into thorax as mediastinal abscesses	Into trachea, esophagus, or through an intercostal space.
	c. Laterally between the longus colli and scaleni muscles.	Posterior to the sterno-cleido-mastoid.
Dorsal	*a.* Burrow posteriorly.	On the back or side; a short distance from the spine.
	b. Within psoas sheath.	Beneath Poupart's ligament in Scarpa's triangle.
Lumbar	*a.* Enter psoas sheath	As psoas abscess.
	b. Burrow between the fasciæ of the quadratus lumborum and abdominal muscles, through the internal oblique.	Posteriorly beneath the external oblique and latissimus dorsi at the outer border of the erector spinæ muscles.
	c. Gravitate beneath the internal iliac muscles over the posterior brim of the pelvis, perforating the great sacro-sciatic foramen.	Gluteal abscess.
	d. May be directed to the iliac region along the aorta and external iliac arteries.	Gluteal abscess.

LYMPHANGIOMA CIRCUMSCRIPTUM.[1]

By M. B. HARTZELL, M.D.,
of Philadelphia.

Under the name Lymphangiectodes, Tilbury Fox first described a curious, chronic, non-inflammatory disease of the skin characterized by the presence of peculiar vesicular and wart-like lesions,

[1] Read before the American Dermatological Association, September 25, 1891.

occurring in groups and patches.[1] Subsequently, Mr. Jonathan Hutchinson presented two cases of a similar kind before the London Pathological Society, naming the disease lupus lymphaticus. More recently a few other cases have been reported, chiefly by English observers—but one, so far as the writer is aware, being found in American medical literature. Because of the rarity and unusual features of the disease, the following case, which has been under observation during a considerable period of time, has seemed of sufficient interest to report:

R. M., a boy, fifteen years of age, has since early infancy had an affection of the skin situated upon the left shoulder, and consisting of a half-palm-sized patch of flat, irregularly shaped vesicles, varying in size from that of a pin head to that of a split pea, arranged in small groups each containing from six to eight discrete lesions. A considerable number of these vesicles, when examined closely, are seen to contain within their interior minute tufts of capillaries, which give to them a reddish hue. These lesions remain unchanged for many months at a time, but gradually disappear through absorption of their contents, new ones appearing from time to time to take their place. The contents of the lesions are a clear, pale-yellow serum. Occasionally, however, owing to the rubbing of the clothing, the minute vessels within some of the vesicles are ruptured, and the contents are then mixed with blood. The disease is unattended by subjective symptoms of any kind, there being neither spontaneous pain nor tenderness on pressure. At no time in the history of the eruption have there been any evidences of inflammation. During the past year, the entire patch has slowly moved anteriorly; the lesions have in great part disappeared from the scapular region, and now occupy the summit of the shoulder. The former site of the eruption shows some slight atrophy of the skin, with faint pigmentation, and here and there a few small, isolated papules. The skin between the vesicles shows no abnormality whatever. The disease was noticed for the first time in the second or third month after birth, the mother stating most positively that it was not congenital. The patient has no other affection of the skin, and has always been in excellent health.

In view of the rarity of the disease, it may be of interest in connection with this case to briefly review the leading features of the small number of cases thus far reported.

CASE I.[1]—The patient was a clerk, twenty-one years of age, born with two large nevi (port-wine stains) on the left thigh. At six months of age the veins of the left calf began to enlarge and became prominent. At the age of two years numerous warty growths appeared on the left buttock, the back of the left knee, and on the left half of the peri-anal region, coincidently with an attack of fever. At the ages of seven, eleven, fifteen, and nineteen years, similar attacks of fever occurred, with enlargement of the lesions and an increase in their vesicular appearance. At the time of the observation, irregular, raised patches were situated on the buttocks and in the left popliteal space, looking at a distance like warty growths, but on closer inspection resembling frog-spawn. The individual lesions looked like small pink warts with vesicular centers. The growth was not affected by pressure, and puncture gave exit to a clear watery fluid.

CASE II.[2]—A boy, ten years of age. The group of spots began with a wart-like spot upon the middle of the chin, one year previously; it spread slowly for a time, and then remained stationary. The patch, the size of a penny, was composed of clusters of small papules, many of which were translucent and contained fluid. The apices of these small lesions were dotted over with minute tufts of vessels. The disease showed great resistance to treatment, which consisted in cauterizations with nitric acid and the actual cautery. Where the disease was not wholly destroyed, it speedily recurred.

CASE III.[3]—A boy, seven years of age. There was a large patch upon the left shoulder which had existed three or four years. The disease was unattended by pain or inconvenience of any kind. The eruption consisted of clusters of isolated and confluent, pale, pin-head-sized elevations, many of them translucent, others blood-stained. The skin between the groups was pale, but otherwise normal. The vesicles contained clear lymph. In many of the lesions minute ecchymoses had occurred, and, in some, tufts of vessels were visible.

CASE IV.[3]—A youth; seventeen years of age. The eruption had existed several years, and was extending. The diseased skin had been the seat of several attacks of erysipelatous swelling.

CASE V.[4]—A girl, seven years of age. The disease was situated over the left trapezius, and consisted of groups of vesicles resembling warts. These vesicles contained clear albuminous fluid, and upon their apices and between them were tufts of capillaries. In close proximity to the large patch were several smaller ones of a similar character.

CASE VI.[5]—A young man, twenty-one years of age, suffered from slight scoliosis and lordosis, with atrophy of the left arm and leg. Groups of vesicles resembling herpes were situated upon brown, slightly thickened skin—in some instances upon normal skin—and occurred, in connection with painful multiple neuromata and cavernous angiomata, upon the left upper extremity, in the region of the brachial plexus. The vesicles were filled with clear serum.

CASE VII.[6]—The patient was a girl, ten years old. At the age of three years, the eruption made its appearance upon the left side of the neck, as a single spot resembling a blister. Within a short

time other lesions appeared, which gradually enlarged, until they became the size of a small pea. At the time of observation the disease consisted of a patch of vesicular-like nodules, closely aggregated. Over some of the vesicles small capillaries were to be seen.

CASE VIII.[1]—A boy, twelve years of age. The disease was first noticed upon the phalanx of the great toe, shortly after birth. At six years of age, other lesions developed upon the leg, and subsequently new ones appeared all the way up to the middle third of the thigh. They slowly underwent involution while new ones were evolved. The veins of the right leg and thigh, the seat of the lesions, were markedly varicose, as were also the circumflex, iliac, pudic, and epigastric veins. No glandular enlargement existed about Poupart's ligament, and there was no discoverable obstruction to the circulation within the pelvis. The cutaneous lesions were situated in the course of and over the varicose vessels. They occurred in groups for the most part, the individual lesions being discrete. These groups consisted of from fifteen to thirty separate, deep-seated, vesicular elevations the size of a pin-head, seated upon normal skin. The contents consisted of a clear, slightly yellow fluid. A few telangiectatic vessels were seen running around the patches.

In addition to the cases detailed, Crocker has reported two, and Walsham one; all three occurring in children, and presenting features similar to those already described.

It is worthy of remark, that in three of the cases the disease was associated with some abnormality of the vascular system. In all it first appeared in childhood, and in the majority in the early months of infancy. The number of cases, however, is yet much too small to permit any trustworthy conclusions to be drawn from these facts.

In the few instances in which microscopic examination of excised portions of the diseased tissue was made, it was found that the principal pathological changes had their seat chiefly in the papillary and sub-papillary layers of the corium. These alterations consisted in the formation of numerous flask-shaped or funnel-shaped cavities containing granular matter, and in some instances, red blood-corpuscles. Langster, who examined lesions from one of Hutchinson's cases, regarded the deeper cavities as dilated lymphatic channels, and the more superficial ones as the result of the distention and rupture of lymph-spaces in the papillary layer. More recently, Török, who examined portions of skin taken from the case reported by Noyes, has expressed the opinion that the process is not simply a dilatation of preëxisting lymph channels, but is a hyperplastic one, leading to the formation of new lymph-vessels.

The only treatment likely to be of service is cauterization by means of caustics or the actual cautery. This should be done in the most thorough manner, care being taken to destroy every portion of diseased tissue. Failure to accomplish this is quite certain to be followed by a speedy recurrence.

ORIGINAL LECTURE.

SIX CASES OF COAL-GAS POISONING, ONE OF THEM WITH AUTOPSY.

BY PROF. J. M. DA COSTA, M.D., LL.D., ETC.

Clinical Lecture delivered at the Pennsylvania Hospital, December 5, 1891.

[Special stenographic report for THE MEDICAL NEWS.]

GENTLEMEN: I shall this morning call your attention to a remarkable group of cases of coal-gas poisoning. There were admitted into the hospital on the first of December six Italians, whose history is briefly as follows: They were all sailors on the Italian barkentine "Selina," lately arrived at this port. On November 30th they had gone to sleep in the forecastle, next to the cook's galley, in which a fire was burning in a stove. It was subsequently learned that it was a stove that had just been purchased, and as the men were not familiar with the management of a coal-stove, they neglected to attach a pipe to it before lighting the fire. As the night was cold, the forecastle was tightly closed. In the morning, as none of the men were out, the captain and mate went into the forecastle and saw them apparently asleep; but they could not be aroused. The hospital ambulance was summoned, and Dr. Miller, the resident physician, accompanying it, upon arrival found four of the men absolutely unconscious, and two merely dazed, who staggered in walking. All six were promptly brought to the hospital.

From this point we will take up the history of these cases in two groups: first the two light cases, and afterward the four grave cases. The members of the first group were, as just stated, not unconscious—they walked, though with a staggering gait; their faces were flushed and wore a stupid expression. The temperature was 99 6° in one case, 100.2° in the other; therefore only slightly elevated. Their conjunctivæ were injected, but the pupils were normal. Respiration was accelerated: in one 24 and in the other 28 to the minute; and the pulse was likewise slightly increased in frequency. Both cases presented extreme irritability; they did not want to be disturbed, and insisted upon being let alone and allowed to sleep. The younger one was absolutely savage when he was aroused. They remained in this mental condition only a short time. The next day they were natural in temper, and the flush had disappeared or was present to only a slight extent; the temperature kept a little above the normal. The urine in both of these comparatively light cases was free from albumin and sugar, and was copiously passed. Indeed, it was healthy urine, except that it contained considerable urates.

As further symptoms in the case of the elder one of the two, G. F., aged thirty years, it should be noted that he complained of much pain in his limbs and in his back; also, though to a less degree, in his

arms. He had, indeed, diffused pains throughout his body, which were not present in the other patient, C. G., nineteen years of age. Both of them presented a hacking cough without expectoration, without change of voice, and without physical signs in the chest.

This was their early history; their subsequent course was as follows: On the 3d of the month (third day in the hospital) the temperature in both was down to normal. The pulse in the younger one showed a slowing, falling soon after admission to 60; this morning it is 68, with respiration 20, and temperature normal. In the second case there was no slowing of the pulse. This morning the pulse is 70, respirations 24, temperature 98.4°. In truth, these men are convalescent. They no longer present any flush; they feel well; they have lost their irritability, and the pains also have gone. A slight cough remains in the first case. The tongue, in Case II, is coated and the bowels are constipated, and, indeed, these have been features throughout the case.

We now come to the remaining group of four cases, which were of a more severe type; for we have broadly distinguished between those in which there is little disturbance and no loss of consciousness, and those in which the poisoning was more decided and with distinct loss of consciousness.

Here is Case III, the first of the series of bad cases. His name is V. V., forty years of age. On admission he presented the same general symptoms as the two preceding cases, except that he was very nearly unconscious, only opening his eyes in a dazed way when he was disturbed, and immediately relapsing into stupor. His face was flushed; the pupils were equal and moderately contracted; his lips were bluish; he had passed urine and feces involuntarily. When he was brought in, his temperature was 101.4°, pulse 110, respirations 24. He remained in the same condition throughout the day, except that he vomited once in the afternoon, about four o'clock, after which he brightened considerably, opening his eyes and seeming more rational. Later in the same afternoon he had two slight chills, and began to cough, bringing up muco-purulent expectoration. He perspired freely about his face and upper part of the body. The next morning, after a fairly good night, he seemed more comfortable, and he slept the greater part of the day. A few dry râles were found in his chest; his respirations were 30, pulse from 90 to 100.

During the day the bronchial symptoms became marked, and the temperature more elevated, ranging between 102° and 103° on the second and third days, declining on the fourth to 99.8°, and finding since its way down to normal; at no time has it been a subnormal temperature. He has perspired freely. The rapid breathing and the râles were never associated with signs of dulness; there was, however, slightly impaired resonance, with congestion of the lung, most marked at the right base. His pulse was weak, as was the first sound of the heart. The urine-record was very instructive. On admission, he was catheterized. The urine was acid, clear, of a specific gravity of 1022, and seemed normal, without albumin or sugar. The urine drawn the same evening was acid, clear, of a specific gravity of 1026, and contained a faint trace of albumin, but no casts were detected. On the second day after admission the urine was acid, very turbid, of a specific gravity of 1024, and showed a little more than a trace of albumin. That morning a few hyaline casts were discovered, with epithelium and abundant urates. Since then the albumin and the casts have disappeared. The urine was examined for sugar on two separate occasions, and none was found. The man has had a great deal of pain in the muscles of the back, arms, and legs. It still hurts him to be turned over in bed and in any way to move his body. His tongue is heavily coated, and his bowels are constipated. His pulse is 86, the respirations are 24, and the temperature is 99°. He coughs and has copious muco-purulent expectoration. He has dry râles at the lower part of the left lung, and rather feeble breathing, with a slightly impaired percussion-note at the lower part of the right lung; in other words, he has still a congested right lung and bronchitis upon the left side. As to the heart-sounds, I find the first sound still feeble; there are no murmurs. The splenic dulness extends just to the margin of the ribs. The bowels are only moved by injections.

Of Cases IV and V, I will give you a brief record. G. T., who is Case IV, is a boy of thirteen years. His face on admission was flushed rather more than in the other cases; he was absolutely unconscious. His pupils were equal, neither contracted nor dilated. He also was exceedingly irritable and restless. His arms were rigid and folded across his chest; there were muscular contractions in the arms. His lips were blue and he frothed at the mouth. His pulse was 132 and weak; the respirations were regular and 24 to the minute; his temperature was 99°. Toward evening on the day of admission he had somewhat roused, but was still restless, showed great irritability when disturbed, and had a frowning countenance. In the evening his temperature was 97.4°, and he was not fully conscious. During the night he refused all milk and medicines. He urinated involuntarily. He had several severe chills and slept poorly, crying out and moaning, and putting his hands frequently to his head, as if in pain; he perspired freely. His condition the next day was more wakeful, yet he was very irritable when disturbed, and had decided muscular pains and soreness. His urine record was as follows: Urine drawn on admission was turbid, 1022, acid, and fairly loaded with urates, but no albumin was found. In the evening, the specimen was turbid, 1022, acid, and did not contain albumin or sugar. The morning urine was turbid, 1026, acid, contained urates in abundance; there was a trace of albumin and some hyaline casts. The next day (on the 3d), his urine was normal and the casts had disappeared. After this he gradually improved; his temperature lowered, but there was again a slight rise yesterday; it went up to 102°, and has remained elevated since. He has some cough, with a few râles, and the same coated tongue and tendency to constipation of the bowels as the other cases. His blood contains 4,040,000 red corpuscles to the cubic millimeter; the white corpuscles are not increased; the hemoglobin is 87 per cent.

Case V is F. C., aged forty-five years. His temperature on admission was 97°, pulse 90, respirations 26. The temperature had gone up in the afternoon to 102°, with pulse 84 and respirations 22, and it remained elevated until the 4th inst., when it descended rather abruptly to the normal. It has since reached 103°. His

face was at first heavily flushed and with a frown on it. He has chest-symptoms: cough, muco-purulent expectoration, with dry and moist râles, but no impairment of resonance upon percussion. He, too, has a coated tongue and constipated bowels and muscular pains and tenderness—these, indeed, in an aggravated form. His pulse was feeble, slightly accelerated—about 80; the first sound of the heart was also weak.

He has an interesting urine-record. As he was unconscious upon admission, his urine was drawn by catheter. It was found to be clear, specific gravity 1024, acid, and free from albumin. The afternoon urine was turbid, 1026, and contained a slight amount of albumin, with hyaline casts, blood-corpuscles, and crystals of urates and of oxalates. The next morning it was again turbid, still albuminous, and contained blood-corpuscles, casts, and oxalates. The following morning the urine was clear again, of a specific gravity of 1022, with traces of albumin, and a few hyaline casts. On the 4th (yesterday) the urine was normal, containing neither albumin nor sugar.

Let us analyze these cases of coal-gas poisoning and view their common features. Five of the six recovered; of the remaining case I will presently show you the specimens. Before proceeding, let me state the treatment that was followed. It consisted in a plentiful supply of fresh air; in oxygen-inhalations to the bad cases; in digitalis, given hypodermatically, to sustain the action of the weak heart; and in stimulating expectorants, especially the syrup of senega, to which late in the case, in a few instances, ammonia was added. The diet consisted of milk. None were freely stimulated except the one that died, but they all had a slight amount of stimulant given, from time to time, when they seemed very weak. Due attention was paid to the condition of the bowels by the administration of salines.

Five of these cases, as I have already told you, are nearly well; it only remains to decide what is to be done for them now. Those that are comparatively free from bronchial irritation, but present coated tongues, we will put upon acid, and administer thrice daily fifteen drops of dilute muriatic acid in infusion of cinchona, two drams. To keep the bowels soluble, we will give a saline—a teaspoonful or more of Rochelle salts each morning in a glass of water. In the cases in which bronchial symptoms persist, we will prescribe muriate of ammonia, 10 grains, in each dose of syrup of senega, which shall be continued. We have no fear now of introducing ammonia into the blood, as we might have had at first. To all of these cases we are also giving from 10 to 12 grains of quinine daily.

This is a most instructive group of cases of poisoning by coal-gas or of carbon monoxide combined with carbon dioxide. These cases are not rare; they are found under circumstances such as these were where the coal-gas from a stove burning in a close room poisons the air. The same kind of cases occur when charcoal fumes are set free in an apartment, which is a favorite mode of committing suicide in France, by leaving a charcoal-stove burning without allowing any vent for the gas to escape from the room. Coal-gas poisoning also happens when, owing to a defective flue, the gas from a furnace passes into a sleeping-room, as occurred in two very severe instances in elderly people, one of which I saw with Dr. James Graham, of this city, a few years ago, and both of which he afterward reported to the College of Physicians.[1]

No matter how produced, the symptoms of these cases are alike. When the poisoning is slight, or the patient not very susceptible to the poison, for some come only slowly under its sway prior to the stage of unconsciousness, there will occur headache, irritability of temper, a disposition to be let alone, and vague muscular pains. On the other hand, when the impression is at once deeper, or there is a longer exposure, the patient lies before you in an unconscious condition. His face is flushed; sometimes, in place of actual congestion or blueness, there is a cherry-red appearance of the mucous membrane. The frown on the face is very significant, and we observed it in all the cases that were unconscious. The respirations are accelerated. An irritative cough is present, and this is more than mere local throat irritation, as several of these cases prove. You will soon find that signs of congestion of the lungs manifest themselves, with bronchial râles and the like. While speaking of the congestion, I told you that it affects both of the lungs; I will now add that the skin on the general surface of the body may also show spots of congestion. There were present in two of the cases (G. T. and V. V.) bluish spots, as if the blood had settled at the lower part of the chest and back, very much like what is often observed *post-mortem*.

The temperature of the cases is peculiar. Two showed depressed temperature (to 97°) for a time, but only early in the case. This leads us to believe that the statement made by some observers is correct, that the temperature in coal-gas poisoning is depressed. But it is not always so, nor, as we see here, does it stay depressed; it soon rises to 102° or 103°, and remains high, especially when there are chest-symptoms. The low temperature is the earliest temperature, and may be of but very short duration. The pulse is accelerated and feeble, and the character of the first sound of the heart corresponds to the character of the pulse.

Let us look at the urine-record. It indicates disturbed action and congestion of the kidneys. It shows albumin, mostly only in traces, though in the fatal case the urine was highly albuminous; in some of the graver instances blood with hyaline casts was present, and, as a very general rule, a heavy deposit of urates, especially of the urate of ammonium, and of oxalates. Sugar we did not find.

With reference to the intestinal symptoms, we were struck with the heavily-coated tongue and the constipation. But far more significant are the general soreness of the body, the muscular pain and tenderness, the desire to keep quiet, to prevent the acting muscles from being brought into play. Undue sensitiveness of the skin did not coexist: free perspiration was common.

I have now grouped all of the symptoms except those belonging to the nervous system. The condition is generally one of deep stupor. The pupils respond sluggishly to light, but are equal and normal. In one of the cases—the fatal case, presently to be described—there were several convulsions; a number showed a

[1] Transactions of the College of Physicians of Philadelphia. 3d ser., vol. viii.

tendency to contraction of muscles. Let me add that general irritability of temper and desire to be let alone existed to a marked degree.

You will ask, What becomes of these cases? When they get well, do they at once get thoroughly well? No! They do not. Indeed, long after the poisoning there may be striking anemia, and fresh nervous disorder may develop. I have already spoken of the case that I saw with Dr. Graham. After she recovered from all of the acute symptoms, on the forty-second day of her illness, aphasia and paralysis came on and remained for weeks.

Before proceeding, I may allude to the fact that the symptoms of coal-gas poisoning may exist in a mild degree from the chronic coal-gas poisoning that goes on in many an ill-ventilated office and room, and headache, depression of spirits, and a tendency to fall asleep are especially prominent symptoms. A very striking instance of the kind is reported by Dr. Woodbury, in the same volume of the *Transactions of the Philadelphia College of Physicians* as contains the report of Dr. Graham's cases.

With regard to the pathological changes caused by coal-gas poisoning, we may see them in the specimens from the fatal case already referred to. The man died with congestion and some edema of the lungs. The notes of the case are as follows:

CASE VI.—F. C., on admission, was absolutely unconscious. The pupils were equal, neither contracted nor dilated; the conjunctivæ were scarcely sensitive; the face was somewhat flushed, lips and ears rather blue; the feet were cold. Temperature 100.6°; pulse 134, very weak; respirations 40, marked by stertor. Muscular irritability was increased, the arms were folded across the chest, and the thumbs strongly flexed upon the palms of the hands; attempted movement of the arms met with powerful resistance. An examination of the chest detected numerous râles. The bowels moved involuntarily twice before admission, and the urine had to be drawn by a catheter. He was given digitalis tincture, 20 minims, with atropine, $\frac{1}{100}$ grain, hypodermatically, because he was unable to swallow. Whiskey was similarly administered, 30 minims every hour, and hot bags were applied to the extremities. He remained most of the day in stupor, with laborious, rather stertorous breathing. In the afternoon, he had slight convulsive movements, during which his breathing became worse; he looked as if he were dying. He was bled fifteen ounces, and oxygen-inhalations were begun, a gallon being administered every fifteen minutes. The breathing improved and remained so for a short time after each inhalation; the inhalations were continued until three hours before death.

The record, made at 6 P.M., was as follows: "Face flushed, ears and lips dark, cheeks puffed out with each expiration, breathing irregular, 46 per minute; râles on both sides of the chest. He is generally quiet, but moans at intervals. There is occasional muscular stiffening, especially in the arms; the hands are bent on the wrists, fingers and thumbs are strongly flexed upon the palms. Pulse weak, irregular, 120 to the minute; temperature 102°. The oxygen acted favorably, causing better pulse and quieter breathing. At 8 o'clock his breathing became much involved and stertorous; he was sweating excessively. He was ordered tincture of digitalis and atropine, as before, with the addition on two occasions of one-eighth grain of morphine. He was much oppressed, and had convulsive tremors.

At 11 P.M. he seemed better; his pulse was 112 and of good volume; temperature 101°; respirations still rapid; but he had opened his eyes and his breathing was more regular. His color was also better, and in general he seemed improved. The oxygen was decreased at this time to one gallon every half-hour. At 11.50 convulsive movements began in the left arm, and then extended to the right arm, finally becoming general; there were rigidity and stiffening of the whole body, accompanied by convulsive movements of the extremities. At 1.25 A.M. (December 2d) he had another and a much more severe attack, lasting fifteen minutes, in which his respirations ran up to 70 in the minute. At 2.30 A.M. he was sweating freely; at 3.25 and 4.25 A.M. he had a hypodermatic injection of morphine, atropine, and digitalis. At 3.30 the temperature was 104.6°, his pulse 160, respirations 40. He was sponged with cool water, after which his temperature dropped to 98.8°, and his respirations were so shallow that he was unable to inhale the oxygen. During the night he had whiskey hypodermatically every hour and digitalis and atropine. After 3 A.M. oxygen was again given, one gallon every fifteen minutes.

The quantity of urine passed in the first twenty-four hours was thirty-seven ounces. On admission it was clear, 1022, acid, and free from albumin. On the evening of the same day it was clear, 1022, and contained a trace of albumin and a few hyaline casts. The next morning it was turbid, 1030, acid, very albuminous (about 7 per cent. by bulk, estimated after boiling), and showed urates in abundance, also a number of hyaline casts and a few epithelial cells; no blood was seen, but many crystals of urates, especially urate of ammonia.

On the second of December he grew steadily worse. The temperature rose to 106° in spite of repeated sponging; it was generally between 104° and 105°, being temporarily reduced by the sponging. He remained in an unconscious condition all day, with muscular twitchings, and at 5 P.M. he had a slight convulsive attack. The hypodermatics of whiskey, digitalis, and atropine were kept up; he perspired a great deal, except directly after the hypodermatic injections of atropine. The breathing continued rather stertorous, occasionally assuming a Cheyne-Stokes character. The pulse remained frequent and weak. At 6 in the afternoon all treatment was stopped, as he was moribund, and he died about three hours afterward."

The post-mortem examination was not made by our pathologist, but by the coroner's physician, who permits us to show you these specimens. Here are the lungs, kidneys, spleen, liver, and heart, and this is the record:

"There was moderate rigor mortis. Hypostatic congestion was most marked on the under surface of the body. The back was reddish blue; this color was also seen on the legs. The examination of the viscera exhibited very little change beyond congestion; they were uniformly congested and bluish, or dark red. The bronchial mucous membrane showed marked redness, and was covered with muco-purulent secretion. There was some edema of the lungs, but, on the whole, not as

much as his breathing during life seemed to indicate. The right heart contained a small, ante-mortem clot; the left ventricle was firmly contracted and empty. The kidneys were much congested, as was also the spleen. The kidneys were examined microscopically, and found not to be in a state of fatty degeneration, a condition which has been stated to be present in poisoning from the carbonic oxides. The blood throughout the whole body was of a lighter color than normal. This was especially so in the lungs, the blood in which was of a brighter shade of red than that usually seen, though not positively scarlet. The blood was also markedly liquid, and the coagula were few and small."

I want to call your attention to the color of the lung-tissue. Of course, the lung is congested but it has not the deep color that the congested lung usually has. It is rather more of a cherry color, such as has frequently been noticed in the cases that have been reported. I regret that the blood was not microscopically examined, but the autopsy was not held at the hospital and we had no control over it. The blood is said to contain hemoglobin deprived of oxygen by the displacing power of carbon monoxide gas, which not only displaces the oxygen, but interferes with further oxygenation—the carbonic oxide having a strong affinity for the hemoglobin, so strong that it suspends the oxygen-absorbing function of the blood—so that it is not merely the case that the blood has been poisoned by absorption of the coal-gas, but this has also seized upon the oxygen in the blood corpuscles, and combined chemically with the hemoglobin, rendering it unfit to further perform its function. You see in this, why it is that the mere administration of oxygen and fresh air is not enough to insure recovery. It was to get rid of the damaged blood that the patient was bled, with the view of taking away some of the devitalized blood; indeed, of not only relieving congestion, but of giving him a better chance to make fresh blood. He was too deeply poisoned to recover. A further point suggests itself in this connection—whether transfusion of blood may be of use. It has been practised and, although apparently rational, it has not been successful. It has occurred to me that we might gain valuable time by practising saline intravenous injections in the severe cases of coal-gas poisoning. This, with previous venesection to remove the changed blood, and with forced feeding, might make new blood so rapidly as to save life. But I throw this out as a suggestion rather than as an expedient actually employed.

CLINICAL MEMORANDA.

TRACHEOTOMY FOR OBSTRUCTION OF THE PHARYNX, WITH REMOVAL OF MUCOUS POLYPS FROM THE NOSE.

BY WILLIAM W. ASHHURST, M.D.,
RESIDENT PHYSICIAN IN THE EPISCOPAL HOSPITAL, PHILADELPHIA.

[Service of DR. THOMAS R. NEILSON.]

ON the night of January 23, 1891, a request came to the hospital to send the ambulance for a boy who was stated to be choking to death from a tumor in the nose and throat. I subsequently learned that this growth had been present for about five years, and had been constantly increasing in size, but it had never before produced any serious discomfort. It had been partially removed two years before, but had soon reached its former size again. Now, within a few hours, it had become so much enlarged that the patient seemed in danger of suffocation.

Not wishing to call out the ambulance for what was probably only an alarm created by the nervous apprehension of relatives, I walked to the house, and found that the severity of the case had not been exaggerated.

The patient, Alexander W., a lad seventeen years of age, was sitting up in bed, supported by pillows, and grasping the bedclothes and mattress with both hands, so as to bring into action the accessory muscles of respiration. He was cyanotic, and, during inspiratory efforts, supra-sternal and infra-sternal depression was very marked. He held his mouth widely open, and upon looking into it there was apparent a prominence of the soft palate downward and forward, forming a vertical, slightly convex wall, not more than two inches behind the incisor teeth. The junction of the hard with the soft palate was marked by a well-defined crease, and between the tongue and the soft palate there seemed to be absolutely no space for the passage of air. Presenting at the left anterior nostril was a mucous polyp, about the size of a small cherry.

Death from asphyxia seeming so imminent, I decided to perform tracheotomy at once. In the condition in which the boy was, any attempt to remove the obstruction was obviously out of the question. With a scalpel from my pocket-case, I cut down on the trachea as rapidly as possible, and opened it just below the cricoid cartilage. What little bleeding took place ceased spontaneously as soon as the trachea was opened, and almost immediately all the alarming symptoms disappeared. As soon as the ambulance could be brought, a tracheal tube was inserted, and the patient was removed to the hospital.

From the time of the operation until the arrival of the ambulance he slept very profoundly, and he remained quiet and drowsy even on the way to the hospital. Upon his arrival there, however, he became very much excited, and, as if in delirium, tried to get out of bed, and showed other evidences of cerebral disturbance. These soon disappeared, however, and in two days his mind had returned almost to its normal condition.

Within a few hours after his admission to the hospital he became able to take liquid nourishment with considerable comfort, so rapidly did the obstruction shrink in size when the dyspnea and the consequent cyanosis and general congestion were relieved.

On January 26th, no unfavorable symptoms having appeared, Dr. Neilson proceeded to remove the obstruction. A considerable quantity of bloody, purulent matter had been discharging from the nose ever since the patient's admission to the hospital, and now the small mucous polyp at the anterior opening of the left nostril had almost completely disappeared. He was etherized by inhalation through the tracheal tube.

It was found impossible to introduce the slender, flexible wire loop of the Jarvis snare, unsupported, past the obstruction; so threads passed from the anterior nares through the posterior by means of a Bellocq's

canula were used as guides, and the wire loop was drawn by this means through the nose until it appeared in the pharynx, below the seat of obstruction. Introducing his fingers into the pharynx from the mouth, the operator now slipped the wire snare around a large growth the root of which was attached to the posterior part of the left middle turbinated bone, and, severing the attachment, removed through the mouth a mucous polyp, ovoid in shape, and about the size of a hen's egg. In the same manner a similar growth, probably even larger, with a corresponding attachment, was removed in fragments from the right nostril, and several smaller ones, the attachments of which were anterior to those of the larger polyps, were removed through the anterior nares.

By means of an insufflator, both nostrils were now coated with a fine layer of iodoform, and plugged anteriorly and posteriorly; both pluggings were secured in place, and their subsequent easy removal assured, by attaching to them strings passed through both nares with the Bellocq's canula.

On January 31st the tracheal tube was removed, and on February 9th the patient was allowed to get out of bed. He was discharged from the house, and referred to the out-patient department, with the tracheal wound closed and the skin healed over it, on March 16th.

It was noticed at the time of his admission that his hearing was very defective; at the time of his discharge, this defect had very markedly improved, although no treatment had been especially directed to the correction of this symptom.

Since his discharge from the house, the extremely hypertrophied left middle turbinated bone has been reduced to its proper size by repeated applications of a saturated solution of chromic acid, and now the chief indication seems to be for an operation to straighten the nasal septum, which is so deviated toward the right as to almost completely prevent a view of the interior of the right side of the nose. Air, however, passes very freely through both nares.

PECULIAR CASE OF PUERPERAL ECLAMPSIA.

By G. A. HEIDNER, M.D.,
OF FREDONIA, WIS.

THE following case seems of interest principally on account of the peculiar onset and character of the convulsions.

Mrs. R., a primipara, was without any history of kidney disease up to two weeks prior to her confinement, or anything unusual during gestation. During the two weeks previous to my first visit, edema, beginning at the feet, had rapidly progressed upward until it involved even the hands and face. The labia majora were enormously enlarged and painful, with serous oozing through the skin.

At my first visit, April 19, 1891, I found the patient as described, and perfectly rational. She assured me that it would be at least four weeks before the expiration of full term. I punctured the labia majora, giving exit to a surprising quantity of serous fluid, and this afforded great relief. I ordered hot fomentations to the edematous extremities, rest in bed, a milk diet, and teaspoonful doses, every four hours, of the following mixture: Tinctura digitalis, ℥ijss; hydrarg. chlorid. mit., grs. x; glycerini, ℥iij; aqua ad ℥ij. The urine was scanty, its specific gravity high, and it contained 25 per cent. of albumin per volume. The bowels were constipated.

At 10 P.M., twelve hours later, restlessness and headache set in, followed shortly by purging and vomiting, and a little later by amblyopia. At 6 A.M. purging and vomiting ceased, but total blindness developed in a few hours, and headache and restlessness became extreme. Twenty grains of antipyrin were given, but were almost immediately rejected by the stomach. About an hour later a hypodermatic of morphine with atropine was given.

The patient had her first convulsion at 9 A.M. The seizure was mild, and did not last more than half a minute. The peculiarity in the onset of this convulsion, as well as in the subsequent ones, was that all the usual prodromata—risus sardonicus, blepharospasm, etc.—were absent. From the usual restlessness she passed into a state of clonic spasm that soon changed to a tonic contraction of all the muscles, producing a rigidity of the entire body with almost complete absence of motion. Cessation of respiration was observed, and no heart-action could be detected. Chloroform seemed of little or no value in these attacks, because there were no symptoms indicating their approach.

Immediately after the first convulsion ended, I gave an enema of chloral and bromide of potassium, of each thirty grains, and telephoned for my colleague, Dr. A. F. Fuchs. The woman had another convulsion fifteen minutes later, from which she went into a comatose state, and did not regain consciousness for twenty-four hours. As she had not complained of labor-pains, I began to consider the advisability of inducing labor. Upon examination, I was surprised to find the os uteri dilated to the size of a silver dollar, and that the contractions were good. A third and a fourth attack occurred at 10.30 and 11 A.M., respectively. The enema of chloral and bromide of potassium was repeated after the third seizure, but could not be retained on account of the descending fetal head, and morphine was, therefore, again resorted to.

The os uteri being fully dilated, and labor progressing satisfactorily at 11 A.M., the patient was anesthetized and kept in this condition until delivery at 11.30. Twenty minutes later the placenta was normally expelled. The post-partum hemorrhage was very light, and the case looked quite promising until 12 M., when, without any warning, a far more serious convulsion set it, followed in a few minutes by another. To all appearances the case was rapidly tending toward a fatal termination. At this juncture the left median basilic vein (the cephalic could not be easily found) was opened, and about eight ounces of blood were withdrawn. Soon, another convulsion came on, much milder than the two just preceding. The pulse still being quite full and hard, six ounces of blood were taken from the right arm. The pulse then became soft. Only one very mild convulsion occurred subsequently to the last venesection. The sedative enema was repeated at 2 P.M., and, as indicated by the restlessness, was repeated at intervals of from one and one-half to three hours until midnight.

At 6 P.M., six ounces of urine were withdrawn by

means of a catheter; the urine contained 50 per cent. of albumin per volume. No microscopic examination was made. The skin was hot and dry, and the temperature 102° F. At this time two drops of croton oil were given by the mouth, and our patient was wrapped in a flannel blanket wrung out of water as hot as the hand could bear, and an oilcloth applied externally to that and closed tightly. The blanket was changed at intervals of from one to two hours. The patient perspired freely, and became much more quiet. The croton oil having produced no effect, a second dose was administered at 11 P.M. *per rectum*. Free catharsis began at midnight and continued for a few days. At 1.30 A.M. a hypodermatic of morphine and atropine was given. On the morning of April 20th the patient was easily aroused, and was quite rational. Vision was beginning to return, but she had no recollection of what had occurred during the preceding twenty-four hours, and would not take her babe. The urine was scanty, of high specific gravity, and contained 50 per cent. of albumin per volume. She was now put on the digitalis and calomel mixture as indicated. There was no lochia.

On April 21st the urine was slightly increased in quantity, and there was some diarrhea; the temperature was 100° F., and the pulse 115.

Diuresis and diarrhea were marked on the 22d. The specific gravity of the urine was 1025; there was 25 per cent. of albumin per volume. Lochia began in the evening with very marked pain over the hypogastrium, which subsided as soon as the flow began. The patient was now put on a tonic mixture, and she made a rapid and complete recovery.

It is to be observed that—

1. There were no premonitory symptoms to indicate the approaching seizures.

2. The convulsive seizures bore no relation to the uterine contractions.

3. Unless constantly inhaled, chloroform was useless in preventing the onset of the seizures, or in modifying their severity.

4. There was great advantage from venesection, the convulsions continuing after delivery, and the pulse being full and hard.

THE APPEARANCE OF NERVOUS SYMPTOMS IN THE EARLY STAGES OF DIPHTHERIA.

BY WILLIAM C. DABNEY, M.D.,
PROFESSOR OF THE PRACTICE OF MEDICINE AND OBSTETRICS, UNIVERSITY OF VIRGINIA.

IT is well known that neuritis, or symptoms pointing to neuritic trouble, occur *late* in the course of diphtheria, or as *sequelæ* of the disease. Two cases have recently come under my observation, however, in which very marked numbness and tingling of the limbs, especially of the arms, occurred at the *commencement* of an attack of diphtheria.

W. M. B., aged ten years, was taken with a sore-throat on October 12, 1891; the false membrane was at first confined to the tonsils and uvula, but the nose subsequently became involved. There was considerable swelling at the angles of the jaw.

On the second day of the attack the boy complained of tingling and numbness in the limbs, especially in the arms, but there was no apparent diminution of tactile sense or of the sense of pain, nor was there any motor paresis. The tingling and numbness, however, were sufficiently great to occasion much discomfort. He was given $\frac{1}{10}$ gr. of bichloride of mercury and 15 drops of muriated tincture of iron, in a teaspoonful of glycerin, every two hours, his throat and nose being thoroughly sprayed just before each dose of the bichloride mixture, with peroxide of hydrogen and water, one part to six. In addition to this, every two hours he took a tablespoonful of brandy in half a glass of milk. The case ran a favorable course, and ended in recovery. The numbness and tingling lasted three or four days, and disappeared gradually. Two weeks after apparent recovery, there was marked paresis of accommodation, but no other paralytic symptoms developed.

The second case occurred in the same family, and was almost precisely similar in character. B. B., aged eight years, was taken sick on November 13th, with severe headache, fever, and sore-throat. There was at this time a small spot of membrane on one tonsil only. With the exception of sore-throat, the only complaint made by this little girl was of numbness and tingling in her limbs; she said they were "all the time asleep." This numbness appeared on the *first* day of the attack, and lasted three or four days, passing off gradually. The false membrane extended to the uvula, and later to the nasal cavity, and there was considerable swelling of the neck. The same treatment was used as in the first case, and the attack ended in recovery. Up to the present time (December 12th) there have been no paralytic symptoms.

The occurrence of numbness and tingling at such an early period of the disease I have not seen before, nor can I find any cases of the kind recorded. It caused me much anxiety, which, as it turned out, was needless, as both cases pursued a mild course and ended in recovery; but my fear was that such marked nervous symptoms occurring thus early might indicate a degree of nervous disturbance that would lead to serious consequences.

ANOMALOUS CONGENITAL FUNCTION: ASSOCIATED SYNCHRONOUS MOVEMENTS OF UPPER EXTREMITIES.

BY S. D. SWOPE, M.D.,
OF MARION, KENTUCKY.

So far as I know, a case similar to the one I report is not chronicled in medical literature.

T. H., a farmer of good habits and healthy family, tall and muscular in form, well developed and healthy, consulted me on April 23, 1891, with a septic wound of the forearm made by a wagon singletree-hook. He explained that the wound had been doing well and, he thought, healing rapidly, until a few days previously when, with the wounded arm in a sling, he attempted to pick up some trash from the ground with the hand of the uninjured arm.

He then explained that all his life whenever he attempted to do anything with one hand or arm, synchronous and similar movements were made with the other hand or arm. This was something new to me and I naturally felt incredulous, but after considerable examination satisfied myself that his statement as to the

anomalous nerve-function was correct. Moreover, this peculiarity was transmitted to three of his eight children. Though the movement of his left hand and fingers gave him much pain, immersed as they were in a hot-water bath, any movement of the right hand or fingers produced synchronous movements in the left. If he raised his right hand to his head, the left would involuntarily move as if to leave the water-bath. If he scratched his head with the right hand, the fingers of the left would move as if in the act of scratching.

His little boy, nine years of age, was called, and on holding his right hand between my palms and directing him to scratch his head with the left, the confined hand endeavored to move, though held firmly. The father, in passing a dish at the table, always takes hold of the table with his right hand to prevent it following the left as the dish is passed. If he carries a basket on his right arm, the left is held in the same manner. When writing with his right hand, the left imitates its movements. In short, whatever his right hand does his left imitates, and *vice versa*.

To keep the left hand immovable, the right must be confined in a fixed dressing.

INTESTINAL ANTISEPSIS IN TYPHOID FEVER BY MEANS OF BISMUTH SUBIODIDE AND SALOL.

BY J. D. FARRAR, B.A., M.D.,
RESIDENT PHYSICIAN, COOPER HOSPITAL, CAMDEN, N. J.

[Service of DR. E. S. B. GODFREY.]

I WRITE in commendation of the plan in practice at this hospital, of giving bismuth subiodide and salol in typhoid fever for purposes of intestinal antisepsis. The test of the accomplishment of intestinal antisepsis is the deodorization of the stools. This method of treatment certainly seems to reduce tympanites, control diarrhea, and prevent hemorrhage—the latter complication being rare when the antisepsis is early secured and persistently maintained. This treatment will modify the severity if it does not limit the duration of the disease. Our rule is to begin the administration of the drugs mentioned, alternately, whenever diarrhea exists, and to continue the same throughout the disease, aiming to keep the stools thoroughly disinfected. Twenty-four cases (six during Dr. Godfrey's term of service) have been thus treated in the hospital, and the foregoing recommendation is the outcome of a study of the results thereby obtained.

A CASE OF CHLOROFORM-POISONING.

BY JULIAN A. HIELSCHER, A.M., M.D.,
OF MANKATO, MINN.

ON September 5, 1891, I was hastily summoned to one of our hotels to attend a travelling man who had tried to commit suicide by taking chloroform. Upon entering the room, a very strong odor of this drug was observed. On the bed I found a man, about twenty-four years of age, in a comatose condition. His face was pale, his respiration very slow and shallow, the pulse imperceptible at the wrists, a cold, clammy feeling of the body and lower limbs, and the conjunctivæ senseless. The pupils were *dilated*. There had been no vomiting, and, as he was unconscious, I could not use the stomach-pump or give an emetic. I then employed $\frac{1}{10}$ grain of apomorphine hypodermatically, which in a short time produced the desired effect. The vomit was almost a gallon of beer (the patient had been upon a spree), which was strongly impregnated with the drug. Being still unable to swallow, I gave him from time to time hypodermatic injections of brandy, and employed artificial respiration, at the same time surrounding him with hot bottles and blankets.

After several hours of this kind of treatment he improved slightly, but not to my satisfaction, and I then administered a quart of strong, hot, black coffee *per rectum*. This acted like a charm; the breathing became more natural, the pulse improved, and consciousness returned. In the meantime I had, by a catheter, withdrawn over a quart of urine, which also emitted the odor of chloroform.

The next day I had the patient removed to Tourtellott Hospital, and a week later I discharged him.

The points of interest are as follows: 1st, the amount of chloroform taken was two ounces; 2d, the time was seven hours after taking before medical aid reached him; 3d, dilated pupils, later on contracted, then natural; 4th, odor of chloroform in urine, breath, and vomit.

MEDICAL PROGRESS.

Excision of an Obliterated Aneurism.—SCHOPF (*Wiener klin. Wochenschr.*, No. 45, 1891, p. 840) has recorded the case of a man, forty-six years old, who presented trophic changes and other evidences of disturbed innervation, circulation, and function in the right arm, dependent upon an obliterated aneurism of the right subclavian artery as large as a man's fist, behind the clavicle and great pectoral muscle. On account of the gravity of the symptoms, in conjunction with a possible doubt in diagnosis, operative interference was determined upon. Artery, vein, and nerves were found adherent. The coats of the aneurism were thickened; the cavity was filled with dense coagula. The afferent division of the vessel was pulsatile and as large as the little finger, while the efferent division was obliterated and reduced to the thickness of a lead-pencil. The former was ligated with strong silk and the aneurism was carefully dissected out. The operation was followed by a disappearance of the distressing symptoms and a resumption of the functions of the right upper extremity.

The Etiology of Posterior Spinal Sclerosis.—ERB (*Berliner klin. Wochenschr.*, Nos. 29 and 30, 1891) has fortified the position that he has taken as to the importance of syphilis as an etiological element in the development of posterior sclerosis. He has carefully studied more than 550 cases that came under his own observation, in almost 90 per cent. of which he was able to elicit positive evidence of a history of syphilis. In the remaining 10 per cent. such a history could not be obtained. To verify the accuracy of his results, Erb made a series of counter-observations in 5500 cases of various kinds of disease, of which it was shown that but 23 per cent. were syphilitic, while 77 per cent. were not syphilitic.

Nearly half of the cases of tabes developed within ten years of the primary infection, while 88 per cent. developed within twenty years. Other causes of subordinate importance, alone, associated, or in conjunction with syphilis, were exposure to cold, excessive muscular activity, sexual excesses, traumatism, and a neuropathic predisposition.

Influenza and Psychoses.—In a paper read before the Medical Society of London, Savage (*Lancet*, No. 3558, p. 1043) quoted the conclusions arrived at by Dr. Leledy in regard to the relation between influenza and the psychoses. 1. Influenza, like other febrile affections, may establish a psychopathy. 2. Insanity may develop at various periods of the attack. 3. Influenza may induce any form of insanity. 4. No specific symptoms are manifested. 5. The rôle of influenza in the causation of insanity is a variable one. 6. Influenza may be a predisposing or exciting cause. 7. In all cases there is some acquired or inherited predisposition. 8. The insanity is the result of altered brain-nutrition, possibly toxic. 9. The onset of the insanity is often sudden, and bears no relation to the severity of the attack of influenza. 10. The curability depends on general rather than on special conditions. 11. The insane are less disposed to influenza than are the sane. 12. In rare instances, influenza has cured psychoses. 13. The insane may have a mental remission during the influenza. 14. There is no special indication in treatment. 15. Influenza may lead to crimes and to medico-legal issues.

Extirpation of a Tuberculous Kidney.—Schuchardt (*Deutsche medicin. Wochenschr.*, Sept. 3, 1891), at the Congress of German Surgeons, reported a case of cystitis in the course of which pyonephrosis developed. Incision afforded but temporary relief. Tuberculosis was suspected, and confirmed by reaction to tuberculin. Other treatment failing, the kidney was removed. Following the operation the excretion of urine was diminished, uremic symptoms appeared, and on the fifth day the urine was suppressed. Death took place on the ninth day. At the autopsy the pelvis of the kidney was found occupied by calculi; the renal structure was almost entirely wanting. Histologically, no changes were found that could be ascribed to the action of tuberculin; the giant-cells were in places disintegrated by the invasion of leucocytes; but bacilli were still to be found. Necrosis of the epithelium of the remaining kidney was the probable cause of the development of uremia.

Chronic Alcoholism with Obstinate Hiccough.—Smart (*Edinburgh Medical Journal*, September, 1891) recently presented to the Edinburgh Medico-chirurgical Society a case of chronic alcoholism with hiccough of three weeks' standing and so obstinate as to prevent sleep and the ingestion of nourishment. Nutrient enemata and suppositories were administered. One-third of a grain of morphine sulphate was injected hypodermatically every three hours; and, to prevent toxic narcotism, chloroform was given by inhalation and by the mouth. At the end of forty-eight hours the patient had obtained seven hours' sleep. By the sixth day the singultus was controlled; by the ninth, feeding by the mouth was resumed, the patient thereafter progressing toward recovery.

The Vapor of Naphthalin in the Treatment of Whooping-cough.—As a result of a considerable successful experience, Chiavernac (*Bulletin Gén. de Thérap.*, 40. liv., 1891, p. 337) recommends fumigation by means of naphthalin in the treatment of whooping-cough. About half an ounce of the drug is, on one or more nights, made to burn in a suitable vessel in the sick-room, the windows and doors being tightly closed. The cough at once moderates, the dyspnea and other symptoms are favorably influenced, and the attack is soon brought to an end. Complications may contra-indicate the employment of the treatment. Thus, individuals suffering with pulmonary tuberculosis cannot bear the treatment.

Congenital Tuberculosis.—At a meeting of the Société de Biologie, Sabouraud (*La Médecine Moderne*, No. 43, 1891, p. 745) presented the specimens of an infant, eleven days old, in which symptoms of broncho-pneumonia had developed on the tenth day. Spleen and liver contained many tubercles with granular degeneration at the center, and containing bacilli at the periphery. The mother had died since giving birth to the child, and presented the lesions of pulmonary tuberculosis, with no involvement of the genitalia or of the breasts. The deduction is that the tuberculosis of the infant was congenital, the infection occurring by the umbilical vein.

The Etiology of Erysipelas.—Jordan (*Archiv für klin. Chirurgie*, Bd. 42) has recorded a case of facial erysipelas, in which there was also a subcutaneous abscess in the frontal region, periosteal suppuration of the right fibula, a disseminated pneumonia of both lungs, periostitis of the pubic bone and of a cervical vertebra, and in which only staphylococci pyogenes aurei were found. A nurse in attendance upon the patient subsequently developed erysipelas; in her case too only staphylococci pyogenes aurei were found.—*Münchener medicin. Wochenschr.*, No. 43, 1891, p. 767.

Albumosuria.—At a meeting ot the Clinical Society of London, Dickinson and Fyffe (*British Medical Journal*, No. 1614, p. 1206) presented a paper containing a report of twenty cases in which the urine contained albumose. It was suggested that what had previously been considered peptone, as found in the urine, was, in reality, in many cases albumose. From the results of experiments upon animals, it seems possible that the diarrhea, from which many of the patients suffered, may have been dependent upon the presence of albumose in the blood. Albumosuria was present in a number of cases of pneumonia of ordinary severity, but it was wanting in some virulent and fatal cases. The origin of albumose is ascribed to the existence of suppuration; its formation is probably dependent upon the activity of pyogenic microörganisms. Albumosuria has been observed in acute rheumatism, especially during the stage of absorption; it was frequently found in pneumonia. It is thought that albumosuria has no connection with disease of the kidney.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 16, 1892.

A NOBLE PROGRAM.

WITH justifiable pride the *British Medical Journal* points to the work in the interest of the medical profession that it has carried out in the past, and looks bravely forward to its coming duties. It aims at a close union for practical work of all the physicians of Great Britain and Ireland, that they may be "bonded together in fraternal coöperation through the British Medical Association, and in direct intercommunication through its *Journal* for the purposes of professional friendship and active influence on the public mind; for social progress, mutual enlightenment, and the attainment of a higher position and of greater influence in the State and in social life, not only for each individual, but for the whole body. By communication and cooperation the medical profession can achieve much more in the future than it has in the past."

That this is not sentimentalism is seen by the plan of campaign laid out for this year. Chief of all is the redressal of the "cruel wrongs and grievous hardships of the Irish dispensary doctors," now "under a singularly inequitable and oppressive system." Next comes the restriction of the patent-medicine disgrace, that is fast becoming a genuine curse of civilization. The reform of the lunacy law is also to be undertaken, and various other needed reforms are to be zealously entered upon.

From the *Journal's* sturdy business-like resolve, with conviction and confidence of success speaking in every line, we turn to our own country to ask if the medical profession here is undertaking the reformation of any such abuses. The reluctant answer must be that there are not the least indications even of the felt need of such work. Individualism, democracy with a vengeance, is the ruling passion. There is little or no united action, no attempt to do away with the wretched abuses everywhere flagrant. There is no common purpose or action toward elevating medical education, toward stopping the execrable shame of the diploma-mills. There is not the faintest hint of a common desire to fight down the national infamy of the patent-medicine business. The ruin wrought by the reckless abuse of hospital and dispensary charity is nowhere more iniquitous than with us. Quackery of a thousand types is nowhere else so rampant and impudent. Insidious or open advertising on the part of physicians has never before or otherwhere been made an art and practice so financially successful and so little rebuked. Europe has laughed into merited obloquy, silence, or non-existence the farce of homeopathy, while here we grant it subsidies from State treasuries, and Fashion dances to feed it with funds. The death-rate of naturally insanitary London, with her five millions of population stewed in vice and squalor, is by sanitation and practical preventive medicine kept far below that of our small cities, with every natural and social advantage favoring them.

But such things must continue until the entire profession of America bands itself together with a common feeling of self-respect and of duty devolving upon it—a duty at once to itself, but also and preëminently to humanity. When such time comes, instead of a multitude of tiny journals devoted to the vanities of editors and writers and to the interests of advertisers, it will then find a few fitting mouthpieces like the two great English medical journals, through which it can speak with power and authority.

AMERICAN PORK IN GERMANY.

THE embargo upon the American hog in Germany was not removed without great difficulty, and the echoes of the struggle are still heard in the public and scientific journals of that country. An interesting and important contribution to the ques-

tion has recently been made by PROF. CARL FRÄNKEL (*Deutsche medicinische Wochenschrift*, No. 51), in which the proposition is maintained that the trichinæ are no longer active, but are practically destroyed in the process of curing the pork as followed in America. It is acknowledged that the percentage of the trichinæ is enormously greater here than in Germany. In the statistics of the Hamburg inspection, given for the six years ending 1883, inclusive, the total figures are as follows: American pork, 235,819 pieces, of which 3470 were infected; German pork, 304,625 pieces, of which 8 were infected. The percentage given by the German inspectors is rather less than that obtained by several observers in this country.

In support of the view that the trichinæ are killed by pickling, FRÄNKEL calls attention to the fact that the countries—such as England, France, Holland, and Belgium—that take a very large amount of American pork annually are almost free from trichiniasis; and he also states that it is doubtful if any well-authenticated instance of infection in Germany can be traced to American pork. In the epidemic at Bremen—if in the Düsseldorf cases—it is not possible to exclude the native pork as a source of infection. In proof of the fact that the processes of curing pursued in this country are, as a rule, fatal to the trichinæ, FRÄNKEL quotes a large number of negative feeding-experiments made by reliable men in Germany and in Holland, and concludes from them that in reality the American is very much less dangerous than the native pork. On the other hand, PROFESSOR FRÄNKEL does not refer to the Havre experiments that appear to show that the ordinary processes of curing have very little influence in killing the trichina, as animals were readily infected when fed with salted or smoked ham and bacon containing the parasites. In fact, the following experiment, given in CHATIN'S work, would indicate that the trichinæ possess a remarkable degree of resistance to salting: On the 19th of April, 1881, a piece was taken from an infested side of bacon, placed in a bottle, covered completely with salt, and the cork sealed. The bottle was opened on the 1st of April, 1882, and the piece removed. After soaking in water for several hours, portions of it were fed to a mouse on the 4th, 5th, and 6th of April. The animal died on the 7th, and perfectly developed sexual trichinæ were found in the intestines. A second mouse fed in the same way died on the thirteenth day.

After all, the important protective measure is thorough boiling or roasting of the flesh, and to this practice is due the immunity enjoyed to so large an extent in this country, in England, and in France, as well as in South Germany. FRÄNKEL urges that the tedious and elaborate inspection that prevails in Germany has scarcely had results commensurate with its enormous cost. That it must be very imperfect is strikingly shown by the fact that the cases of trichiniasis, numbering yearly in North Germany at least 100, are all caused by eating the flesh of animals that have undergone inspection. It is also disadvantageous in giving to the people a dangerous confidence in the soundness of the meat, and encouraging them in the habit of eating it raw or only partially cooked. In the districts of Münster 250 inspectors in six years examined 118,000 swine with the result of finding only one trichinous animal. The conclusion of the whole matter, so far as Germany is concerned, is that the people should give up the practice of eating uncooked meat, whether native or American.

Coming from such a recognized authority, PROF. FRÄNKEL'S article will no doubt be widely read, and is one of the most favorable that has appeared in defence of that much-abused and long-suffering animal, the American hog.

AMEBIC DYSENTERY.

WITHIN the past eighteen months, since the detection by OSLER of the ameba coli in this country, the question of its relation to dysentery has been carefully studied and its presence determined by MUSSER, STENGEL, and others, in Philadelphia, and by DOCK in Galveston. An elaborate monograph on the subject recently issued from the Johns Hopkins Hospital by COUNCILMAN and LAFLEUR (*Johns Hopkins Hospital Reports*, vol. ii, fasc. 6–9), is the most valuable contribution to the clinical history and morbid anatomy of dysentery that has been made since the publication of WOODWARD'S exhaustive treatise in the medical reports of the War of the Rebellion.

The study is based upon fifteen cases. The general clinical review by LAFLEUR, PROF. OSLER'S assistant, is a clear and convincing statement in support of the view that amebic dysentery is a form of dysentery separate from ordinary catarrhal dysentery, and also from the diphtheritic varieties. Among the special features are the more chronic

course, the numerous intermissions and exacerbations, and the tendency to serious complications, particularly abscess of the liver. The stools in a case of moderate severity are stated to be liquid, brownish-yellow in color, containing mucus and streaks of blood, sometimes sloughs. There is less viscid, clear mucus than in ordinary catarrhal dysentery, and, as a rule, much less blood. As a case becomes more chronic the stools no longer have a dysenteric character, but are of the consistence and appearance of thin gruel. The reaction of the stools is generally alkaline. Frequently, attacks of constipation alternate with diarrhea. The amebæ are found in all varieties of the stools, and at all periods of the disease, being most abundant in the exacerbations; they may be present even after the evacuations have become normal. The amebæ can be readily seen, and move actively at the ordinary temperatures, though the motion is accelerated on a warm stage. The authors hold that the characters of the stools of catarrhal dysentery and of diphtheritic dysentery are different; the amebæ were not found in the twelve cases of catarrhal and three of diphtheritic forms that were under observation at the hospital. Tenesmus was absent in many of the cases, and the fever, as a rule, was slight, and in many instances transient. The complications of the series were most important, as may be judged by the fact that abscess of the liver occurred in three cases, abscess of the liver and of the lung in four cases, peritonitis with perforation once, without perforation once, and intestinal hemorrhage twice. Of these complications the abscess of the liver is most important, and was usually characterized clinically by pain, irregular fever, with sweats. In the hepato-pulmonary abscess, of which four cases are given, the sputa are almost pathognomonic, as originally noted years ago by BUDD, who states that "there is no matter like it expectorated in any disease of the lung itself." It is described as often bright-red at first, subsequently of a dull brick-red, brownish-red, or rusty-brown color. Amebæ are present in it, occurring in considerable numbers. They are constantly found in the liver-abscess associated with this form of dysentery, as first pointed out by KARTULIS. The description of the anatomical lesions is elaborate, and is illustrated by seven double plates, giving the histologic details of the changes in the intestines and in the liver. The conclusion is reached that the ulcers in the colon in this form differ from those in other varieties of dysentery. The ulceration is caused by infiltration of the submucous tissue and necrosis of the overlying mucous membranes, and there is, as a rule, an entire absence of the products of purulent inflammation. The amebæ exist in numbers throughout the coats of the intestines, and in two cases were found in the peritoneum. In one case there were found throughout the liver numerous miliary abscesses, all of which, even the smallest, contained amebæ in numbers.

The life-history of the parasite remains to be worked out. KARTULIS has been able to cultivate the organism, but it is an extremely difficult matter to get pure cultures of the protozoa. It is most natural to suppose that the amebæ reach the intestines with drinking-water, probably in an encysted stage, in which they can resist the action of the gastric juice.

The disease is very chronic, and characterized by a special tendency to relapse. The treatment suggested is large rectal injections of bichloride of mercury (1 : 5000 and 1 : 3000), and injections of a solution of quinine of varying strength (1 : 4000 to 1 : 1000). Although the series of cases studied by these authors was unusually severe and the mortality high, in several instances the disease ran a mild course, and was rapidly relieved by the injections.

SELECTION.

SO-CALLED "HYDRARGYRUM LACTATUM."

A CASUALTY from the misuse of drugs is reported from Bay City, Michigan. Somebody blundered, and somebody else lost his life; so says the *Western Druggist*. A physician of that town fell into the habit of prescribing "hydrargyrum lactatum," meaning thereby a preparation furnished by a Chicago dealer in drugs, which is said to contain one part each of calomel and of bismuth subnitrate, and eight parts of milk sugar. This did no harm so long as the prescriptions were taken to the shops where the Chicago specialty was known. But the day came when a change in pharmacists was made by the patient. The new pharmacist ordered through his wholesale dealer a bottle of "hydrargyrum lactatum," and received a supply of Merck's "lactate of mercury." Merck's catalogue contains that item, with the price marked at $1.00 an ounce. Chemistry recognizes "hydrargyri lactas," or mercurous lactate, and, although it is not often heard of in medicine, Watts's *Dictionary of Chemistry* describes its composition and properties. This preparation was dispensed three times before any injurious effects were noticed, but the fourth dispensing of it was followed by the death of the patient. An analysis of the drug is said to have shown the presence

of mercuric lactate as well as of the mercurous salt, and it is suggested that a reduction had been going on in the bottle after it left the wholesaler's hands. If this is the fact, and can be proved, it will tend to lighten the condemnation launched by the *Western Druggist* against the conductors of the Chicago drug-house for its "criminally reckless terminology," in that they adopted a harmful name to cover a comparatively mild "specialty." It will also tend to lighten the feeling of responsibility for this particular "accident" in the mind of the physician, against whom the *Druggist* alleges that his conduct was "little less than criminal," because he prescribed a substance about which he really knew nothing. There seems to be a fatality about nearly all these "specialties, or combinations made by some known-to-us-alone process;" sooner or later, they become the occasion of loss of life, or they get everybody into trouble who has anything to do with them. The remedy of known composition is not always safe, but it comports more thoroughly with the dignity of the profession to employ it, so that even if perchance a casualty should follow its legitimate use, it will not be necessary to resort to that most idiotic of excuses, "I did not know it was loaded"—the plea of those who point pistols at their best friends and kill them!—*New York Medical Journal.*

CORRESPONDENCE.

PSYCHOLOGIC ASPECT OF THE "KEELEY CURE."

To the Editor of The Medical News,

Sir: There are some facts connected with this so-called "cure" that are worthy of the consideration of the medical profession. There are other phases that need but little investigation to warrant utter condemnation. Only a brief consideration of the medicinal agents used is necessary; it does not matter much just what agents are used. The sciences involved in the education of the liberal physician have something of a materialistic tendency, and we, as a profession, are prone to consider as of prime importance tangible material and obvious agencies of forces.

But we must not overrate the potency of material agents, neither must we ignore forces and agencies that we are cognizant of only by the light of reason and logic. It is not necessary to go over the ground of the pathologic anatomy of alcoholism. The physician knows the structural changes in the various organs and tissues of the body brought about by the habitual use of alcohol. He also knows that structural alterations in the brain, spinal cord, liver, kidney, and heart, are not overcome by any medicinal, mental, or moral methods of treatment.

As to the therapeutic application of the salts of gold, there is no new field of applicability. This auriferous element has without doubt more potency in the hand than it has in the stomach or in the circulation. The gold salts are acknowledged to be inferior to the iron salts in therapeutics. From a study of the physiologic action of the terchloride of gold, Hoffman, twenty years ago, conceived the idea that it would be of use in alcoholism, but careful and honest experiment and clinical use failed to give any evidence of a utility greater than that possessed by the iron salts. From time to time the medical profession has had its exacerbations of "auric fever," but it has always been a self-limited disorder.

Who knows that in the so-called "gold cure" gold is used at all? A patient is injected with a solution, but who knows its analysis? The patient receives hypodermatic treatment and ceases to have an appetite for spirits. Why? Is it because the solution of some salt of gold circulating in the system has restored normal function to a cirrhotic liver, or rendered an inflamed stomach more anemic, or caused a cardiac hypertrophy to disappear? Is it because a human being, weakened physically, mentally, and morally by alcoholic excess, is suddenly converted by having a drug administered to him? Nothing like this. Nothing new, or occult. There has been no newly-discovered potency whereby we can so easily set at naught Nature's decrees. The pathologic changes brought about by excesses are not to be remedied in a day or a month by any agent at our command, or that we shall ever command. There are effects, however, produced by drugs on systems thus depraved. It is a well-established therapeutic fact that certain drugs for a time lessen the craving for alcohol.

Hypodermatic administration of certain cerebral and cardiac stimulants, such as strychnine, atropine, cocaine, and digitalin, will stimulate the cardiac and nervous system to a degree sufficient to render alcohol superfluous and even objectionable to the patient. What, then, are the important factors that Keeley uses? For we do not question but he has effected cures of dipsomania. Whether the patients lapse again, it does not matter, unless the lapse be immediate. If a person affected with dipsomania has his appetite allayed for a year, it is fair to say that he is cured so far as the craving is concerned.

We all know the mental condition of the inebriate. All physicians have seen the poor unfortunate one on the verge of delirium. They have seen how the intellectual faculties and perceptions are blighted. They have seen manhood shorn of its glory. They have seen that apathetic dependence on the decrees of fate, that intellectual inertia, consequent upon frequently repeated stimulation, and it is a psychologic fact that a mind thus weakened is more susceptible of receiving and accepting suggestion than one in possession of natural moral and mental vigor. The susceptibility of the human mind under certain conditions of accepting suggestion is known to every observer of life. We know that changes in belief may be brought about, and even sensations due both to functional and organic disease may be so far ignored or forgotten as to *cease to be sensations.*

We will not go into the details of hypnotism, or hypnotic suggestion, except in so far as it has to do with the subject in hand. The phenomena of hypnotism were never so clearly understood by the scientific world as they are to-day. It is the province of psychology to reveal the laws governing these phenomena, and it has been the function of this branch of science to lift the veil of obscurity, remove the charlatanism, and dispel the dogmas that have clung to this department of mental science for many years. With the fair-minded there no

longer remain the delusions with which the mesmerists of one hundred years ago surrounded the phenomena of hypnotism. We now disclaim magnetism as a factor in the production of the hypnotic state, and deny that only a certain few persons who claim to be endowed with extraordinary will-power are capable of inducing hypnosis. We no longer use the magic wand or the "luminous shadow" of Lord Lytton to induce somnambulism or catalepsy.

The authority alone of reputable specialists is sufficient endorsement for the facts of suggestion, and there are scores of men that have seen epileptic seizures prevented, the hallucinations of melancholia relieved, and paralyses of months' duration immediately overcome by simple verbal suggestion.

But there is nothing in this beyond the comprehension of common mortals, if they will honestly consider all of the circumstances. If by a simple word of command a cerebral tumor that gave rise to epileptiform seizures had disappeared, or had trophic changes in an atrophied muscle been thus brought about, then we could justly consider such powers with awe; for we might then consider them supernatural. But the modern physician is denied any such supernatural power. The therapeutic application of hypnotic suggestion depends for its exercise upon an exact knowledge of definite but not occult physiologic and psychologic functions that any person of fair intellectual attainment can possess.

As suggestion is the factor in the production of the hypnotic state, so it is capable of producing a state of *susceptibility* entirely apart from lethargy, somnambulism, or catalepsy. This fact was pointed out by the school of Nancy, many years ago. The therapeutic application of suggestion has, as a basis, the fact that many diseases of a functional nature can be cured or relieved by making the patient believe that a cure will be effected if the advice given is followed. In other words, we induce a state of credulity. And this fact is the explanation of another, one that is as old as disease, and as well known to every physician as the phenomena of respiration, viz., that the specific treatment of certain diseases is moral, and that, whatever else it may be, any form of medicine is a placebo. But it is necessary that this state of credulity be induced, and there are cases in which it is impossible for the physician to implant this faith without first using some material means of producing an impression on the system, though the effect may have no direct bearing on the disease to be cured. These are the facts taken into account in the recent methods used in the cure of dipsomania.

In his rational and sober moments, the poor unfortunate sees his downfall, he sees the "handwriting on the wall," and he is willing and anxious to be restored to manhood, to family, and to society. He will avail himself of any opportunity for such restoration.

He goes to this wonderful healer and receives his injections and *mirabile dictu!* his thirst is lessened. The stimulants have done the initiatory work. The heart that has contracted feebly without alcoholic stimulation now pulsates more strongly under the effect of higher potencies. His tremor is lessened, and this he sees and takes courage; he feels that he is to be cured, for others have been cured in the same way. His mind throws off its lethargy, and he is all hope and determination. After a few such stimulating injections, together with the assurance of friends and of the physician, he believes, beyond any possibility of doubt, that he is to be free from desire for alcohol. He is convinced that alcohol is a poison and has no use in the animal economy.

That cures of dipsomania have been effected by Keeley, we do not deny.

That the hypodermatic injections are a factor in the cure we do not deny. But we assert that the chief factor is *suggestion*.

Very sincerely,

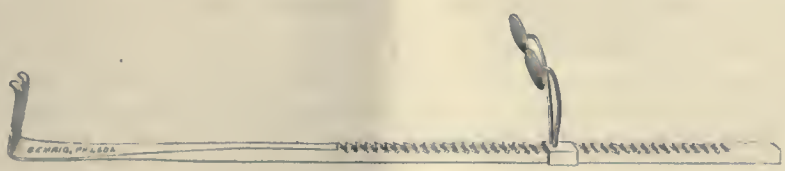
G. M. RANDALL, M.D.

AUGUSTA, MAINE.

SELF-RETAINING PALATE-RETRACTORS.

To the Editor of THE MEDICAL NEWS,

SIR: In an article by Dr. T. H. Weagly, of Marion, Pa., on "Self-retaining Palate-Retractors" (THE MEDICAL NEWS, September 5, 1891), which escaped my attention at the time, I see the following: "For thorough examination of the posterior nasal cavity and for various operations therein, such as the removal of adenoid tissue, galvano-cauterizations, and many of hypertrophied turbinates, the need of an effective self-retaining palate-retractor has long been recognized, both by surgeon and specialist. To meet this want the White Retractor, shown in Fig. 2, was brought out," etc.



As a matter of fact, the first description of any instrument of the kind ever published was one devised by myself and published in the *N. Y. Medical Record*, January 14, 1888, with cut, and in the *Transactions of the South Carolina Medical Association* for April, 1888, and in a *Handbook of Diseases of the Nose and Throat*, by Carl Seiler, M.D., third edition, p. 63. Full credit for priority of publication was also given by Dr. Joseph White, of Richmond, Va., in the first description of his instrument. The accompanying cut will illustrate the difference between the two instruments, that represented in the figure being only a slight modification of the first instrument described.

As shown, the hook being a solid band instead of a wire loop, the tissues cannot bulge through and obstruct the view; and the tip being bifurcated and curved backward, the septum is neither scraped nor injured, but serves to steady the instrument. The catch on the slide is entirely automatic in its action, without screw or clamp. The arms are provided with metal or hard-rubber pads, and rest on the alveolar processes outside of the nose. They are securely retained there

by the pressure of the retracted palate, and never slip unless improperly adjusted. In addition, as they do not enter the nose, they can always be applied to any face without regard to configuration, etc.

A rather recent experience has served to impress upon me the great utility of these retractors. It was in the case of a patient to whose pharynx I made a galvano-caustic application, relying for guidance through the nose upon the irregular outlines of the inferior meatus. The result was a severe attack of otitis media acuta with diminished hearing and consequent great mental distress for a period of several weeks. The incident will effectually prevent me from ever making any application of a similar nature without the aid of a retractor and consequent absolute accuracy by ocular demonstration.

W. PEYRE PORCHER, M.D.

CHARLESTON, S. C.

ELECTRICITY IN "LA GRIPPE."

To the Editor of THE MEDICAL NEWS,

SIR: It is probable that every practitioner of repute in this city (and also in all other large cities) has his own method of managing influenza, and the variety of remedies employed, as seen by the files of the druggists, would lead an acute observer to think that the *specificity*, as a friend called the disorder, is more apparent than real, and that possibly a less varied and elaborate therapy would do as well in the cure of the unfortunates as that now suggested by writers, which includes almost all of the new remedies, and a big lot of the older ones.

My own list of drugs has been very small, and most of my cases get well as soon under little medication as those who have been thoroughly soaked with stimulants, antipyretics, sedatives, and deobstruents. Partly because I am using electricity in some form of disease liberally every day, and partly because it is so well adapted to relieve pain, at least temporarily, I have tried what could be done with the different currents in this troublesome affection, and it gave good results in the few instances in which it was employed. The first instance was that of a woman who had great soreness and pain in every region, but particularly in the legs and back, and with her I used galvanism, both generally and centrally, running the current up to twenty-five milliampères. The first sitting gave her decided relief, and with the exception of the cough, which lasted for three days after the other symptoms disappeared, she was practically well in twenty-four hours after beginning the electricity. The next patient was troubled with the pain more particularly about the occiput, and had considerable sickness of the stomach and high temperature with it. A galvanic current applied to the nape of the neck (positive) and (negative) to the epigastrium, under an ascending current of thirty milliampères, relieved the nausea at the first application, and dissipated the weariness and pain at the second, while the cough also was notably improved—ceasing in four days without any expectorant or other drug whatever. This person was unable to rise from bed when I saw her first, and was apparently very seriously ill, yet she lost all of the prominent symptoms in the short time indicated.

The next case was that of a child who suffered distressingly from the throat and chest symptoms—her influenza being as pronounced as in any of the instances in which my patients have been sick for a fortnight or more. I gave her a little fever-mixture, and applied galvanism to the pneumogastric—positive to the neck, negative to the solar plexus. The electricity was not given until my second visit, at which time she had not been relieved at all by the medicine taken; the first application shortened the paroxysms of sneezing and coughing fully one-half, and the next in the evening still further improved her condition, not alone as to the thoracic symptoms, but in all respects. Half a dozen applications settled the matter, and converted what was apparently a very threatening case into one not at all alarming, and in a week she was out and at school. The three were typical instances of grippe, and no one could tell from the outset, as far as symptoms were concerned, how bad the trouble might be in the future, yet each did well under electricity alone, for all the medicine, aside from the galvanism, was inconsequential. Might I ask my friends who are equipped with suitable apparatus to try galvanism? I am now looking into what faradism and static applications will do in this matter.

"DISPENSARY ABUSES."

To the Editor of THE MEDICAL NEWS,

SIR: I am moved by the refreshingly vigorous editorials on "Dispensary Abuses," which have appeared recently in THE MEDICAL NEWS, to say a few words on this subject.

In the issue of January 2, 1892, you call attention to the tremendous falling off in the subscriptions on the last "Hospital Sunday" in London, and characterize this as an indication that public benefactors and philanthropists have had their eyes opened to the misuse that is constantly being made of their contributions. As an illustration of the extent to which this is done, and of the effrontery practised in the misapplication of funds donated for charitable objects, I would call attention to one of the annual reports issued by the oldest dispensary in the city of New York. We are told by the Board of Trustees that this dispensary had treated during the year 38,699 new patients, and a total of 102,818 cases; and in the same report the house-physician says: "All patients applying for treatment have received it *without question as to their ability to pay* [italics mine] for the services of an outside physician, and thus many have doubtless abused the charitable object of our institution." This statement has the merit of candor, if nothing else, but it becomes the height of impudence when it is associated in the same report with an appeal to the charitable for contributions, in which it is stated that the dispensary "assists the taxpayers in diminishing pauperism, and consequently crime," and helps "the poor to be self-supporting." It seems almost incomprehensible that shrewd and successful business men should put their hands into their pockets year after year to support such "charities," and allow statements like those quoted to pass unchallenged. Of course, the managers of these institutions seldom make the mistake of allowing their

house-physicians to print such reckless statements, and, consequently, those who are called upon to contribute are not often made acquainted with the true state of affairs. Again, is it not remarkable that, although the report to which I have referred was published and circulated two or three years ago, there has been no serious effort on the part of the trustees of this dispensary to remedy the evil? Surely this is an abuse of the funds entrusted to their care, and, as the gentlemen constituting the board of trustees are well-known and honored business men, we can only explain their failure to act because of the well-known and almost proverbial apathy of boards of managers.

Your closing remarks in the editorial referred to carry a stinging rebuke to many a young physician in this city; but do not blame them too much for their often unwilling part in encouraging "a cowardly sort of socialism," and for degrading their profession, until you have succeeded in so impressing the older and more influential members of the medical profession with a sense of the great wrong that they are constantly perpetrating upon their young professional brethren, and upon society at large, so that they will be willing to take the lead in this much-needed reform. O.

NEW YORK CITY.

"SCARLATINIFORM EXANTHEM."

To the Editor of THE MEDICAL NEWS,

SIR: I read with interest Dr. J. Madison Taylor's note on "Scarlatiniform Exanthem," in THE MEDICAL NEWS of December 19, 1891. It seems to me that the case is probably one of erythema exfoliativum. There is an interesting paper on the recurrent form of this affection, by Dr. Henry William Blanc, in the *International Clinics* for October, p. 348.

I am very glad to see the description of any of the exanthems that resemble scarlatina, as, under the most favorable circumstances, there is much difficulty in making the diagnosis, and I believe much confusion exists in the minds of many members of the profession as to the difference between scarlatina and some of the other exanthems. The scarlatiniform variety of rubella very closely resembles scarlatina in its general appearances, and one is very frequently taken for the other. Very often an attack of erythema from indigestion is mistaken for scarlatina, but much more frequently a mild attack of scarlatina is pronounced roseola or erythema from indigestion.

When we consider the serious consequences that may follow even the mildest attacks of scarlatina, the importance of an early diagnosis is obvious, and I would be glad to see all questions relating to the diagnosis of these diseases discussed at length in the journals.

Yours very truly,

WHARTON SINKLER, M.D.

1600 WALNUT STREET, PHILADELPHIA.

THE PERCENTAGE OF ALBUMIN IN URINE.

To the Editor of THE MEDICAL NEWS,

SIR: I was much pleased to read in THE MEDICAL NEWS, G. M.'s criticism of the careless habit prevailing among medical men of speaking of the percentage of albumin in urine. I have written and spoken so much upon this subject that I hesitate to take up the matter again lest it be regarded tiresome, although I seem to have made a very limited impression. It is true, as G. M. says, that the *blood* contains but 8 per cent. of albumin, and as the albumin of albuminuria comes from the blood, more than 8 per cent. is impossible, whereas in point of fact 2½ per cent. is about the maximum noted. What the writer meant, of course, was 50 *per cent. of the bulk* of urine tested. As the time, trouble, and apparatus required render it practically impossible for the vast majority of physicians to use the gravimetric method for albumin, and as appliances like Esbach's albuminometer are inaccurate, we must, for the most part, continue the method of measurement by bulk, which is, indeed, sufficiently accurate for practical purposes. If men will only say 25 per cent. or 50 per cent. of *bulk*, as it may be, they will be beyond criticism, although I think it better to retain the percentage expression only for *weight*, and to speak of *one-quarter bulk* or *one-half bulk*, as it may be.

JAMES TYSON, M.D.

"ARTIFICIAL EYES INSERTED WITHIN A WEEK AFTER ENUCLEATION."

To the Editor of THE MEDICAL NEWS,

SIR: I observe a note on the early insertion of artificial eyes by Dr. G. M. Gould. May I be permitted to observe that I have been in the habit of ordering artificial eyes for patients who live at a distance, to be inserted within seven or eight days after the operation. In some instances they have been used sooner. I have followed this plan for several years. I have learned that when they are inserted and worn regularly at so early a date a chronic and annoying conjunctivitis is almost certainly set up. To avoid this, I am particular to insist that the eye shall only be worn when in public for two weeks, that it shall be removed and laid aside for a day or two if any irritation arises, and I prescribe a boric-acid lotion to keep the conjunctival sac sweet.

G. STERLING RYERSON, M.D.

60 COLLEGE STREET, TORONTO, CANADA.

NEWS ITEMS.

Medical Legislation in the United States in 1891.—Among the laws of interest to the medical profession passed during the year, we may mention the following: The Immigration Law passed by the last Congress requires medical inspection of all immigrants on arrival. All idiots, insane persons, paupers, or persons likely to become public charges, or persons suffering from loathsome, dangerous, or contagious diseases, as well as felons and assisted persons, are to be sent back to the country from which they came.

Congress has also passed an act establishing five stations for the inspection of meat that is destined for export. The principal duty of the inspector appears to be to search for trichinæ.

The State of Alabama has passed a law requiring all physicians who are not graduates of reputable medical colleges to obtain certificates of qualification from a board of medical examiners.

The State of Arkansas has passed a law allowing the Board of Medical Examiners, after trial, to revoke the license of a physician to practise, if convicted of unprofessional conduct.

The State of Nebraska has passed a law requiring a certificate from the State Board of Health and graduation from a legally chartered medical school or college, before a license to practise is allowed.

Among the States in which bills regulating the practice of medicine have been defeated, may be mentioned Massachusetts, Rhode Island, and Pennsylvania. The latter State has already a registry law. Massachusetts is now one of five States only in which the practice of medicine is unrestricted by law.

The New York State medical practice law, passed during the preceding year, went into effect. It provides that no one shall practise medicine in the State without previously obtaining a license from the State Board of Medical Examiners.

In Massachusetts a law was passed requiring the detention of inmates of State penal and charitable institutions who are suffering from syphilis in a contagious form until the disease is no longer contagious.

The State of Maine requires all persons having charge of infants with sore eyes to report the fact to physicians. It has also passed a law to provide for the registration of vital statistics.

In Massachusetts an attempt was made to restrict the use of arsenic in the manufacture of various articles, but it resulted merely in prohibiting its use in children's toys and confectionery.

The United States Supreme Court has decided that a court may not order a medical examination of a person in a civil case, against his or her will.

The Municipal Court of Boston has decided that a druggist may sell cigars on Sunday, as a drug to be used for the cure of catarrh.—*Boston Medical and Surgical Journal.*

The Outcome of a Malpractice Suit.—The complaint in a suit against Dr. William T. Bull, to recover damages for malpractice, was recently dismissed in a New York court. The suit was originally brought againt the New York Hospital for an operation that it was complained was not successfully performed by Dr. Bull. The verdict on this issue was for the hospital. Suit was then brought against Dr. Bull, with the result stated.

A Journal of Pathology is about to be published at London. The new journal will be under the editorial charge of Dr. Sims Woodhead, who will be assisted by the principal pathologists of Great Britain and Ireland as collaborators and co-editors.

List of Medical Journals.—Dr. Ferdinand King proposes publishing in an early edition of *The Doctors' Weekly* "a complete list of medical, dental, pharmaceutical, veterinary, and scientific journals."

CORRECTION.

In THE MEDICAL NEWS of December 12, 1891, p. 688, in the clinical memorandum "Chloroform-poisoning," it should have been said that *apomorphine* was injected hypodermatically to produce emesis—not pilocarpine.

BOOKS AND PAMPHLETS RECEIVED.

ORIGINAL ARTICLES.

LATE SYPHILIS.[1]

BY P. S. CONNER, M.D.,

PROFESSOR OF SURGERY IN THE MEDICAL COLLEGE OF OHIO AND IN DARTMOUTH MEDICAL COLLEGE; SURGEON TO THE CINCINNATI HOSPITAL, ETC.

MORE than any other disease, not excepting tuberculosis or carcinoma, syphilis is the common meeting-ground of us all, physicians, surgeons, obstetricians, specialists, pathologists, sanitarians.

Practitioner or philosopher, it matters not, there is to each a mighty interest in the study of the nature, the action, the effects, of this scourge of humanity. Modified, attenuated by transmission through a dozen generations, it is still a dreadful and a dreaded ill. Were there only the early lesions, the primary sore, the cutaneous efflorescences; the mucous erosions; did it run its course in weeks or months; were its subjects then left well, changed only as one is changed after an attack of vaccinia, syphilis would take its place among the minor ills, not altogether an ill, for there would be secured by its passage through the body protection for the future. And this is its history in a large proportion of cases. Because of the action of the normal law of infectious diseases, and doubtless still more because of a widespread, may it not be said universal, syphilization through the centuries, the intensity of its action has been so lessened that in two-thirds, it may be four-fifths, some would have us believe nine-tenths, of the cases to-day, the duration of the attack may be measured by weeks, at least by a few years, and its severity is so slight that we might almost speak of the benignity instead of the malignancy of the disease. To say with even close approximation to truth what proportion of cases end with the superficial manifestations is impossible. Hospital statistics are of little value. Oftentimes, patients in the early stage of the disease are excluded. Generally, only in limited number are they compelled to cease work and be cared for in the wards. As a rule, those that ask public assistance are wanderers, whose life-history cannot be traced, who not seldom are, first and last, at many hospitals, or they again and again appear at the same hospital, to swell the numbers and vitiate the statistics. Nothing could more conduce to error than to take the reports of any institution, or any set of institutions, and base a conclusion upon figures as to the actual ratio of organic lesions to early manifestations.

The case-books of specialists will not furnish the required data. The masters in this department of surgery must have under care organic lesions far in excess of their actual proportionate occurrence. The ordinary practitioner of to-day can seldom furnish the desired information, for of his *clientèle* it may largely be declared "*varium et mutabile semper.*" The family physician who has known his cases from the cradle to the grave may tell us much, but he is fast passing away, and is even now but occasionally seen.

Careful examination of the sick-reports of armies having long terms of service would be of great value. As it is, though we are each largely influenced by personal observations, the almost universal feeling is that in about three out of four, or four out of five, of the acquired cases, the disease is short-lived, and does but little damage.

Unfortunately for the prognosis in any given case, there is nothing in either the character, the extent, or the intensity of the early symptoms, nothing in the course and duration of treatment, that makes it certain that in time all will be well with the individual, that either spontaneously or by art the disease will in time have become eliminated. Nothing except a reinfection can make apparent that it is not merely latent, to reappear at some distant day. But it certainly is hard to understand how it is that the milder the earlier manfestations the greater is the liability to the occurrence of grave late lesions. Is the poison eliminated through the cutaneous and mucous rashes and patches? Are not such eruptions indices of the intensity of infection? As a rule, are not the later symptoms and sequelæ of other infectious diseases milder and more likely to be escaped when there is little disturbance at first than when it is otherwise? Who regards a child as better and for a longer time protected against variola, that is, its system more thoroughly infected by vaccinia, in direct proportion to the fewness of vesicles and the absence of local and constitutional disorders?

Those syphilitic by inheritance suffer from the late lesions in far greater ratio, and this cannot surprise us when regard is had to the developmental

[1] Read at the Congress of American Physicians and Surgeons, September 23, 1891.

activity of intra-uterine life, and the usual impossibility of therapeutically affecting the disease during that stage of its evolution.

It is with the smaller fraction of cases in which there is something more than superficial manifestations — with the organic, destructive, deforming lesions, with the affections that may not show themselves for many years, with "late syphilis"— that we have now to do.

Neither chronologically nor anatomically is there a sharply-defined line of demarcation between the early and the late constitutional symptoms. The one may be indefinitely prolonged, the other very early manifested; cutaneous and mucous lesions may not be confined to the first months or years; the visceral affections may be synchronous with, or even precede the common eruptions. But, speaking generally, there is a pathologic distinction of great value: the late lesions are neo-formative; the early hardly ever so; the late so largely gummatous that the gumma is the sign and seal of the tertiaries. Further, they are not communicable.

As a rule, to which, however, there are not a few exceptions, the late lesions are quietly developed, their existence often announced only when destructive action has produced its effect in irreparable loss of substance, Nature having made no effort to expel the disease, which, no longer a foreign, toxic intruder, has become a part and parcel of the economy. Rarely are the new formations observed before the the end of the first year; they rapidly become more frequent up to the end of the third year. Comparatively seldom are they first developed after the close of the fifth year.

Only with life itself ends the possibility of gummata forming in one who has acquired syphilis, and even when the disease is inherited the outbreak may be delayed until the body has reached its full maturity. No region, no organ, no tissue is exempt from invasion, with resulting new-growths in mass diffused, or in the arterial walls. Of most frequent occurrence, and therefore of greatest interest, are the affections of the bones and of the nervous centers—the first known from early times, the second recognized and understood only within the period of our own lives.

That the skeleton should be attacked is not surprising, when its structure and functions are remembered. Bone is not, as all are more or less inclined to regard it, mere formed material serving for support, protection, and muscle-attachment, but in its more important, physiologically more valuable part, it is formative, a species of lymph-gland, liberally supplied with blood, and active in effecting those corpuscle-changes on the perfection of which depends the health of the whole body. If this is so, why then, it may be asked, is not its affection an early one, and not a lesion of advanced syphilitic life only. Is it not so?

Besides the well-known characteristic osteocopic pains and periosteal swellings of brief existence, are not a few of the feebler, more diffused, more fugitive aches in leg, chest, and head, not a little of the general weakness and marked anemia of the first months, due to infected blood passing through the bone-vessels (the swollen, irritated lymphoid cells resulting, a part of the general adenopathy) and to the impairment of the functional value of the bone activity? Coming on at an ill-defined later period, the new formations are in those parts in which normal cell-changes are most decided, the vessels of which are most abundant, and that are most subject to the action of slight traumatisms, tendon-strains, and atmospheric influences.

In this, syphilis is like tuberculosis and osteomyelitis; and in the resemblances in location and course of specific bone-disease to the other affections just named, may there not be found reasons for believing that, like them, it is of mycotic origin, the definite organisms of which may not long escape detection?

The lesion may be single or multiple, confined to a single bone or present in many, asymmetrical or symmetrical. That there is occasionally affection of corresponding bones on both sides of the median line of the body, either synchronously or in quick succession, is a fact, though without doubt it is exceptionally so, in marked contrast to the symmetrical manifestations of the earlier period.

The three varieties of bone-inflammations are present as in no other disease; a rarefying, condensing, and developing osteitis occurring together, in the same bone it may be, much more often in separate parts of the skeleton more or less remote, or following each other at variable intervals of time. Excluding the bones of the head and face, the affected parts of the skeleton rarely show the molecular destruction of caries in comparison with the death in mass of necrosis, and even the latter is ordinarily limited to but a small part of the tissue involved (the sequestrum seldom being of any considerable size) and more often due to excess of reparative action, than to a primary cutting off of the blood-supply.

Liquefaction is rarely observed and true suppuration only as an accident, when there is an added infection by the pus-formers. Rarefaction and condensation go on together to an extent unequalled in any other form of bone-inflammation, and such marked association may be accepted as strongly indicative, if not absolutely demonstrative, of specific nature. New formation of bone on the interior, the exterior, and at the ends of the diaphysis, is a common result; but, as a rule, the weight

of the deformed bone is not proportionate to its size, and not seldom it falls below the normal, so great has been the rarefaction, which may, and at times does, reach such a degree that fracture follows slight violence or muscular action. Such lesion may be the first observed indication of existing syphilis, and its occurrence should always excite marked suspicion whether the subject of it is adult or child. Very possibly there is something more than simple rarefaction in these luetic bones that makes them so brittle, the strengthening fibers not only being few in number but each and all abnormally weak as a part of the general depravity that belongs to syphilis.

In the long bones it is above rather than below the epiphyseal line that the inflammation is, as a rule, located; hence the comparative infrequency of secondary joint-affection; though the gumma may form under the encrusting cartilage, and by its resulting destructive action upon a part of the articulating surface, or later by pushing its way into the synovial cavity, it may set up joint-disease, specific or common, that, unlike the bone-inflammation, is often suppurative. Curiously enough it is not absolutely certain that such disease will follow the intrusion and prolonged residence of the gummatous mass in the joint-cavity. The frequency of periosteal disturbances, both early and late, exudative and gummatous, may be due not only to a primary infection of the affected area, but to extension to it from the interior of the bone along the Haversian canals or the tissue in the extra-epiphyseal region to the deeper layer of the periosteum, the continuity of which is a demonstrated anatomic fact. Were as careful examination made of the bones of syphilitics as of their throats, lungs, or livers, it is highly probable that osseous lesions, congestive, exudative, and neo-formative, would be found to be of great frequency—existing often when not at all suspected. As ordinarily seen at the present day, extensively destructive and deforming bone-inflammations are almost confined to the head and the nasal regions. It is but rarely that there is found one of those greatly enlarged, rough, as it were worm-eaten and stalactite-covered long bones that are so common in the museum collections of forty, sixty, and one hundred years ago. The reasons for this are not far to seek. The disease is milder, the patients are better fed and better housed, the proper treatment is more systematically and thoroughly applied. Even in the vault of the cranium great gummatous ulcerations and mortifications are not so very often met with, and in the sternum they are surgical curiosities. Yet these are the bones in which the serpiginous and tunneling advance of the morbid process can most freely take place. It is in the skeleton of the nose and parts adjacent, that specific caries and necrosis are most common, the reason for which is (in large measure doubtless) found in the exposed position of the bones, the thinness of some of them, the unusual abundance of small vessels as compared with the number of main feeding-trunks, and the intimate fusion of mucous membrane and periosteum. No better illustration could be found of the oftentimes insidious symptomless course of gummata, than is afforded by many cases of these naso-pharyngeal affections, the existence of which may be revealed only after large tracts of bone have become necrotic. In the adult and when acquired, there is seldom difficulty in recognizing the specific nature of the lesion, except in those cases primarily epiphyseal and later involving the joint, in which a preceding syphilitic course cannot be ascertained, either by tracing the history of the patient or carefully searching for the physical evidences of cutaneous or deeper affections. In such cases the diagnosis must rest upon the slowness of development, the non-existence of rheumatic or tuberculous disease in other parts of the body, the absence of pain except upon pressure, and then only in limited and fixed areas, the slight impairment or non-impairment of the joint-motions, the failure of ordinary therapeutic measures to effect relief, and the decided, often rapid, benefit from the administration of the iodides. In cases by inheritance, especially when the infantile manifestions have been slight and the bone-disease appears at eight, fifteen, or twenty years of age, its specific nature can be easily, and again and again has been, misunderstood.

Though a very large proportion—nine-tenths or more—of chronic bone-disease and joint-disease, in the child, the adolescent, and the young adult, is tuberculous, yet the cases in which it is of syphilitic origin are by no means few. How may they be recognized?

1. By location. The lesion is in all probability in a long bone, not an irregular one, not a vertebra, not in the tarsus or the carpus, but in the tibia (and this above all others), or in the femur or a phalanx. If in the long bone it is much more probably in its diaphysis than in the epiphysis. Take away the cases of affections of the articulating extremities of the femur, the tibia, the humerus, the forearm bones, how many cases of tuberculous disease of the long bones would remain?

2. By recognition of traces on the cornea, the teeth, or the skin, of previous syphilitic affections, and that, too, perhaps in one markedly hard of hearing, and evidently feebly developed.

3. By application of the therapeutic test.

4. When practicable, by inoculation. Of course, if it can be determined that one or both parents

were syphilitic before the patient was born the difficulties of diagnosis are greatly lessened.

The most frequent, the most dangerous, and until recently, the least understood lesions, are those of the nervous system, to which "syphilis is a veritable poison." In the intensity of brain-activity and the necessarily correlated, always abundant yet never constant, blood-supply, is found the explanation of the fact that in one-third of the cases of tertiary lues decided disturbances of motion, sensation, or intellection are observed; taking no account of the irritative neuralgias, the cries for healthy blood, that more or less severe, more or less fugitive, are seldom or never absent in the earlier months. Rarely found among the inherited affections of children, nerve-syphilis attacks men much more often than women, and especially seizes upon the brain-workers, those engaged in professional or literary pursuits, or such business as calls for undue, irregular and quick use of the organs of perception and feeling. Alcoholic poisoning, with its alternating mental exaltations and depressions, and its slowly advancing but certain and permanent arterial degenerations, strongly favors its development. Any debilitating cause of long continuance increases the liability to its manifestation, and not least among them is malaria. The new-growths, here as elsewhere, diffused, circumscribed, or in the vessel-walls, are seldom of large extent, are likely to be multiple, and occur in regions in direct proportion to their vascularity, *i.e.*, to their functional value; much more often, therefore, on or near the surface, than deep in the substance of the nervous mass. Their effects are due to pressure, to involvement and consequent destruction of tissues of importance, to irritative and inflammatory changes around and about, to the direct or indirect impeding or cutting off the inflow, or much more rarely obstructing the outflow of blood from a given area, to (but only exceptionally) extravasation from a thinned and dilated artery. These effects—in other words, the various morbid phenomena observed, the pains, convulsions, pareses, paralyses, vertigos, failures of the special senses, disturbances of sleep, of thought, of memory, coma—are in themselves in no respect different from those produced by non-syphilitic causes.

It is upon associated conditions of age, of general health, of antecedent history, of previous attacks, of transitory course, of combined, perhaps strangely combined morbid conditions, of remissions or intermissions, spontaneous or therapeutically secured, that the differential diagnosis is based. The new-growths, whether in the meninges alone, or in both envelope and cortex, must follow the same course as similar formations in other parts of the body—occasionally becoming spontaneously absorbed, at times liquefying, even perhaps to the extent of producing cysts, giving no evidence of their specific origin, more often reduced in size, or, unfortunately not very often, entirely removed by proper treatment, producing limited cerebral softening because of the anemia consequent upon vessel-obliterations or plugging, or the specific irritation-changes outside of the infected area—such changes being more dangerous than the growth itself, the the pressure of which increases so slowly that the brain can readily accommodate itself to it.

In his address at the Berlin Congress, Mr. Horsley, speaking of the cerebral gumma declared that "Medicinal treatment in nowise cures, and only very temporarily alleviates the trouble. . . . Excision offers the only chance for the patient." Is this the fact? Has not again and again much more than very temporary alleviation followed the administration of the iodides, with or without the mercurials, in cases in which there was present every ordinary indication of the existence of an intra-cranial gumma? However great the advances of brain-surgery in the last few years, would not the outlook of a syphilitic be much worse than it is, if only in the exposure and removal of the gumma could be found a chance of recovery? To be sure, he is much more likely to have a sclerotic patch than a distinct tumor, but on the other hand a pre-operative diagnosis between the two lesions is not always easy, and is not seldom impossible.

The affections of motion, of sensation, and of intellection are frequent, in the order given. The first, at some time or other, in some degree or other, are present in every case. The second—far more often on the side of diminution than of excess (for hyperesthesias, except as neuralgias and headaches, are comparatively rare)—are frequently absent, and if they exist, are commonly of but moderate intensity. The third form but a small part of the lesions under observation, whether one looks for impairment of memory, for change of temper, for more or less decided melancholia or mania, for the grave and inevitably lethal symptoms of general paralysis, or for the obscuration, partial or total, of coma that so often presages speedy death.

The disturbances of motion may show themselves either in increase or in diminution of movement, in convulsions or in paralysis. That epileptiform seizures should frequently occur is only what might be expected. The motor area of the cortex is a region of great functional activity, consequently of very numerous bloodvessels; as a necessary result, new-growths in abundance are developed and meningo-encephalic adhesions are formed, and excitation by irritation or pressure very naturally follows. Though occasionally generalized and like common epilepsy, the disease is far more often very akin to the Jack-

sonian affection; so much so, that recognition of its specific nature oftentimes is not made—sometimes, perhaps, cannot be. But convulsions very rarely appear for the first time in early or middle adult life, except as the result of traumatism; occurring primarily after fifty, they are of grave import with reference to general paralysis, or organic disease of the kidney or heart. It is in the interim between the time of the attacks of childhood and of approaching old age that the syphilitic seizures occur; and this fact is of much diagnostic value—enough, almost to establish specific nature in the absence of other evidence.

Hysteria may mimic syphilis, as it does so many other affections, but it is of infrequent occurrence in men. Brain-syphilis, in any of its manifestations, is comparatively seldom seen in women, and the hysterical disorders of sensation are not present.

The paralyses are much more common, constituting, it has been estimated, one-fifth of all paralyses observed, and, speaking generally, are of graver import than are the convulsions, since, aside from certain of them occurring early, they are indicative of more extensive new-growth or more destructive lesion of adjacent parts.

Pareses rather than paralyses exist in many cases; these motor disturbances are strangely combined, often intermittent, not seldom one-sided, passing at times from one side to the other, either quickly or only after the lapse, it may be, of many months of marked improvement, or even of entire relief of symptoms. Coming on slowly as a rule, with no antecedent apoplexy, arresting, at times completely, the action of a single muscle or set of muscles, while slightly impairing that of others near or far away; attacking the ocular muscles, the nerves, of which the third, fourth, and sixth are rarely involved in the paralyzing lesions of other origin; preceded oftentimes by prodromal cephalalgias of decided, even intense, severity; frequently, on the other hand, associated with no material disturbances of sensation, the mental faculties remaining, in general, unaffected; often yielding readily to treatment, early and thoroughly applied, incapable of change for the better when due to destructive softenings or cicatricial repair-changes; these paralyses, by their location, extent, and time of appearance, are ordinarily readily recognized as of specific origin, and serve as indices of the parts of the brain especially diseased. They are often associated with marked affection of the speech-center, or at times with disturbances of the special senses; aphasia and sense-impairments being ordinarily incomplete, fugitive, intermittent, recurring, it may be, only at irregular and remote intervals.

Sensation, frequently unaffected, certainly in any marked degree, may be diminished or exaggerated. The agonizing headaches of the earlier stages of the disease, when they are often of cranial rather than of cerebral origin, are not so very seldom equalled by those associated with the late deep-seated lesions; and at times there are observed severe, lasting facial neuralgias from involvement of the fifth nerve within the cranium. The special senses share, but in a much less degree than might be expected, in the sensory disturbances of the intra-cranial affections. In by far the larger number of cases of specific blindness and deafness, the producing lesion is located in the orbit and in the ear.

Disturbances of intellection, to the extent of somewhat enfeebled mental action, especially on the side of memory, are of such common occurrence that they may be regarded as almost necessarily associated with any and all of the brain-lesions. They are due, in great measure certainly, to the disturbed circulation within the cranium, and are matters of little moment, being often simply expressions on the part of the cerebrum of the general depression that syphilis always produces. In a limited number of cases, the psychic disturbances are much more positive. The subjects of them become unfit for business, are excessively irritable, markedly melancholic, actively maniacal, or even seemingly demented. Many of them become general paralytics; and a large proportion of those having this almost certainly fatal affection have a syphilitic history, though the specific poisoning has been only one of the depraving conditions that have brought about the mental state. In all the psychic affections in which clear evidence cannot be found of a limited, circumscribed brain-lesion, anti-syphilitic treatment, instead of proving beneficial, is positively injurious.

In certain cases—fortunately they are very few—most marked motor sensory and mental disturbances occur, suddenly and simultaneously; the patient being found, ordinarily after sleep, in a state of stupor, from which it is usually possible to arouse him, but only partially, it may be but for the moment. The muscles of the extremities are all thoroughly relaxed, as are also those of the bladder and rectum. Sensation is greatly impaired or abolished. The pulse-rate is decidedly lessened, the breathing is slow, and the temperature is sub-normal. This syphilitic coma may or may not have prodromata, sensory or motor; may come on in those in whom the syphilitic disease is active or latent; may appear early or only many years after the primary infection. It may terminate in speedy death or in recovery, which is often followed by recurrent attacks, sooner or later destroying life.

Under a mercurial treatment, promptly and vigorously instituted and persistently maintained for many months, relief, even permanent, may be expected and secured.

Spinal lesions are of infrequent occurrence, both actually and as compared with cerebral lesions. As cranial exostoses may press upon the dura, so may vertebral outgrowths press upon the adjacent membranes, and the spinal canal being narrow, a mass of moderate size may cause destruction of the contained cord, directly by compression, indirectly and more often by interference with the blood-supply. Neoplasms in the meninges or in the cord itself will by pressure produce pains in the affected area or at the remote points of nerve-distribution; and paralysis, according to size and location, limited or extensive, of a single muscle or set of muscles; or hemiplegia, paraplegia, it may be of trunk, arms, and legs, due either to compression or degeneration of the cord. The associated sensory disturbances may be slight or severe, intermittent or fugitive, on a paralyzed side or on the opposite, but the deeper situation of the gray matter always protects in greater or less measure against its compression, still more its destruction.

A question of much interest is that of the causative relationship of syphilis to locomotor ataxia. Is this disease one of the late specific spinal lesions? That the majority and a large majority of ataxics have at some time or other had syphilis cannot be questioned. It has been declared that a syphilitic history is more often found in connection with tabes than a rheumatic history is found in connection with disease of the heart. But tabes certainly is not of true gummatous origin, nor can the sclerosis be regarded as the result of the diffused formation so often found in the cerebro-spinal axis. Syphilitic treatment generally, may it not be said always? fails to cure—may not even retard the evolution of the symptoms. In no small number of cases there has been no luetic infection, and when there has been such, view the disease as we may, locomotor ataxia can only be regarded as a sequel, not a lesion, of syphilis; bearing perhaps, as has been suggested, some such relationship as post-diphtheritic paralysis does to diphtheria, though it is much easier to understand an early-displayed paralyzing action of the ptomaïnes of an infectious disease than such action manifested five or ten or twenty years after apparently complete subsidence of all local symptoms.

If either the time or the occasion permitted, consideration might well be given the lesions of other parts, of skin, of throat, of lung, of liver it may be, lesions always gummatous in character and destructive in effect. Everywhere and at all times a manifestation of late syphilis means danger to part, danger to life; the latter, while often escaped, not seldom becomes a reality to the fullest extent.

How are we to understand year-long intermissions, with after-development of grave functional and organic disturbances? With the disappearance of an unimportant syphilide, the young man seems to be free of his malady. In physical and mental health he passes the years of maturity, and sturdy children, without spot or blemish, grow up around him. When fifty or sixty or eighty years old, it may be, with the changes inseparable from advancing years, there appear organic affections that are unmistakably specific. Such cases are rare, very rare, if you please, but they nevertheless exist. Where has the disease been in hiding all these many years, and in what shape? Recurrences take place in other affections, but do they closely resemble these late manifestations of syphilis? The adult that in childhood had a white swelling, a hip-disease, or a caries of the spine is very likely to die of pulmonary tuberculosis before he has passed middle life; but the exciting organism has been encapsulated in the primarily-damaged area, and has been set free by a breaking down of the fibrous and osseous envelope, or, without direct relation to the primary lesion, the bacilli have come in from without, producing not a reinfection, but a new infection, and the disease so developed passes through its regular stages from the very first, or the lighting up anew of morbific action in the long-encapsulated mass has caused a new synovitis or a caries, in no respect different from the original. In a femur or tibia that was affected by an osteomyelitis of adolescence, suppurative osteitis may show itself years later. Here there has been a setting free of pyogenic organisms long imprisoned in the bone, or as a place of least resistance the bone has again inflamed under the action of such organisms taken up anew from a distant felon or abscess or ulcer, and carried along in the blood-stream.

The individual from whom a scirrhous breast has been removed may have malignant disease of the bronchial glands, of the stomach, or of the liver after several years of apparent health; but the places of detention and the route of infection can be found and traced. In each of these diseases the recurrence is like the original attack, differing only in the extent and rapidity of its action. Not so with syphilis. There is in this long-delayed manifestation no first or second stage, no initial lesion, no roseola, no mucous patch. Without any inaugurating local or general disturbances there is developed a gumma. Is this the reproduction under the influence of irritation of unknown character of the original chancre, the cutaneous papule, or the temporarily enlarged glands? It is simply, we are told, another step in the advance of the disease arrested for an unusual time at its second halting-place—such arrest, in and of itself, no more strange than the arrest for hours of an attack of intermittent fever. But in this latter affection, when the new start is made, the old cycle is travelled again, the

symptoms are general; and the same may be true if the intermission has been of months' or of years' duration.

But in syphilis the new disturbance is confined to a very limited area—in a bone, in the rectum, or in the cranium—in which, in many cases certainly, there had been no previous disease, at least no evidence of such. No other part of the body may ever be affected; the lesion is purely local. What developed it? A specific organism long dormant at the spot? If it were so, would there not have been in the remote antecedent period of syphilitic activity some evidences of the non-specific overgrowth required for its encapsulation? Consequent upon its presence, would there not have been in the part something more than a fugitive, ill-defined ache? And even this is frequently absent. Is it a poisoning product, like a ptomaïne, of the earlier action that, after long presence in the blood, is carried to the seat of the late manifestation, and there excites the new-formation? Can anyone understand a poisoned state of the blood that is continued through years, the septic chemic agent remaining unchanged, or constantly reproducing itself or being reproduced, without there being any manifest symptoms of departure from the normal standard of health, until at a far distant day it causes a syphilitic new-growth in some part or other?

What is the morbific agent? what suspends its action? where is it stored? what so late starts it up into destructive activity in only one direction, ending in one product, whether the period of latency has been one year or forty years—the same, indeed, if there has been no "sleep-time" after the disappearance of the cutaneous congestive or exudative lesions, and the disease has passed directly from stage to stage? Are there not in this course of syphilis questions of intense interest relating to nature and action—problems well deserving consideration and solution, if solution be possible? But there are other questions that may well be examined—questions of fact, but not respecting the character, location, or effects of lesions.

What are the relations of syphilis to other diseases and to injuries? How is it affected by them and they by it?

Preëxisting tuberculous disease, because of the general weakness induced by it and the lessened power of the cells to protect themselves, renders probable a more severe, often a more rapid, syphilitic course. It is not necessary that such disease should be manifestly active. To the "strumous" individual, other things being equal, a specific infection is always more dangerous, both in the extent and destructiveness of lesions, than it is to others. In negroes and mulattoes, in our country, the severity and, yet more, the persistency of lues, especially in its glandular enlargements and its external gummatous ulcerations, are due, it may well be believed, to the tuberculized soil upon which the specific virus has been implanted, fully as much as to irregular living and neglect of treatment. Certain lesions are more common in tuberculous than non-tuberculous persons, such as the gummatous stenoses of the alimentary tract, especially of the esophagus and rectum.

That specific lesions may become tuberculized has been proved by the occasional bacillary infection of syphilitic lupoid tissue; but only very rarely does the tubercle-bacillus find a nidus in and about a syphilitic new-formation. A partial explanation of this lies doubtless in the fact that in the great majority of cases tuberculosis of parts other than the lungs has been produced, or is likely to be produced, only at an age antedating syphilitic infection, or at least the period of the late manifestations.

Syphilis is not likely to be inoculated upon an individual suffering from carcinoma; and if it is, there is no good reason why the two diseases should not go on each in its natural way. But carcinoma may attack an area in which there have long been specific thickenings and indurations, as in the chronic leucomata of the tongue, in the same way and for the same reason that it is often a direct consequence of non-specific irritative epithelial overgrowths. Occasionally, a gumma undergoes carcinomatous degeneration, more often when situated in the substance of the tongue than anywhere else, and the local affection, no longer amenable to specific treatment, advances steadily from bad to worse, the neighboring gland or glands soon becoming infected, and death resulting at no distant day from weakness, from hemorrhage, or from visceral disease. In certain localities, especially in the breast, a gumma may readily be mistaken for a carcinoma, and in not a few instances the mamma has been removed because of the existence in it of a mass that would have disappeared under treatment by the iodides. If syphilitic growths do not become sarcomatous, they often much resemble sarcomata, and many a reported successful operation for the malignant affection has been really one in which a gumma has been removed. Particularly has this been true of tumors in muscles, and in the orbital cavity.

How does syphilis affect wounds, and how do traumatisms affect the disease? As a rule, the wounds of syphilitics, when the affection is in a passive latent stage, heal as promptly and as kindly as those of others, though union may be delayed or even be prevented until after the patient has been brought under the influence of the anti-specific remedies. This is much less true of wounds of the soft than of the hard parts—*i. e.*, fractures, in which, in

spite of the most judicious treatment, at times false joints will form. When the specific lesions are in process of active evolution, it matters not whether early or late, the chances of interference with proper repair are not few, and no operation should be performed at such a time that with safety can be postponed. Indeed, at any time before performing an operation the success of which depends upon the securing of primary union, it is well to keep the patient for several weeks under the influence of the iodides and mercurials. Very rarely, under any circumstances, does a wound become actually syphilitic.

In one who has had the disease, even though there may not have been a manifestation of it for years, any traumatism may be the starting-point of extensive specific lesions. On the other hand, when the individual becomes syphilitic, an old scar or fracture-callus may break down, just as it may under the influence of scurvy.

Is aneurism in comparatively young subjects, say under forty, consequent upon syphilis? Always? No. In very many cases? In all probability. As one of its most marked effects, the specific disease unquestionably produces endarteritis; and, though this inflammation especially attacks the medium-sized and smaller vessels, it is not limited to them, and the weakening of the walls that it produces cannot but predispose to fusiform or sacculated dilatation.

As respects life, is syphilis a grave disease? Very much so in its inherited form, its lethal influence being exerted from the moment of conception. Four-fifths of the pregnancies terminate prematurely, and of the children born alive the great majority die within a few weeks or months, or at most years. But not seldom after cessation of manifestations, in the intervals of manifestations, or even in the very late tertiary stage, the spermatozoids and ova are sufficiently free from syphilitic influence to permit of the begetting of healthy children. But acquired, in adults, the mortality-rate is very low—how low it is impossible to state, vital statistics on this point being, for obvious reasons, defective and unreliable. In our census report for 1880 it did not reach one per thousand of the whole number of deaths from known causes. How seldom in private practice has it happened to any one of us to have a patient die of syphilitic lesion?

Clinicians, medical and surgical, have learned very thoroughly the coarse lesions, and pathologists the structural character of the new-growth in organs and tissues. Practitioners, general and special, are in unusual degree in accord as to treatment, even as to the extent to which it should be carried. The professional work of the future must be chiefly that of the microscopists, the bacteriologists, and the medical chemists. In the laboratory, not at the bedside, will be revealed the secrets of nature, growth, dissemination, and influence.

If it be possible, sanitarians and political economists have before them the task of working out some practical and practicable plan of controlling the spread of this disease, that damages the young, weakens the strong, infects the innocent, diminishes the results of labor, increases the poor-rates, keeps down the population—that is everywhere and in all respects destructive to the private and the public weal.

ELECTRO-THERAPEUTICS IN AMERICA.[1]

BY A. D. ROCKWELL, A.M., M.D.,
OF NEW YORK.

IN complying with the request of the President of this Association, that I prepare a paper dealing with the earlier work of my late associate Dr. Geo. M. Beard and myself in developing the field of electricity in medicine, and in securing for it professional recognition, I beg in the beginning to bespeak your patient forbearance toward what might under other circumstances seem an undue amount of personal reference. A little more than twenty years ago, electricity was but another name for quackery. When the writer first ventured to present for the consideration of the Medical Society of the State of New York a paper on the "Medical Use of Electricity," an eminent physician on the committee exclaimed: "What, is he regular?" At that time, to call oneself an electro-therapeutist was to confess guilt of the grossest ignorance and fraud. To-day all this is changed. Electricity has followed in the footsteps of our permanent specialties and occupies a position of assured respect.

One of the first in this country to call attention to the use of electricity in medicine was Dr. Thomas Brown, of Albany. In a little work entitled "*The Ethereal Physician*," issued in 1823, he recommended franklinic electricity for paralysis, tic douloureux, epilepsy, chorea, and various other diseases, and a year subsequently a Dr. Everett, of New York, contributed to medical literature his own experiences in the same direction.

Although some good was accomplished, electricity was found to be a most uncertain remedy.

How, indeed, could it be otherwise? Induction electricity had not yet been discovered, and both the old cylinder static machine and the voltaic pile were uncertain and inconstant in their action. All efforts at this time, therefore, for the purpose of

[1] Read at the first annual meeting of the American Electro-therapeutic Association, held at Philadelphia, Sept. 24, 1891.

giving importance and dignity to electro-therapeutics signally failed, and it was not only neglected, but fell into absolute disrepute. But when induction electricity was discovered by Faraday, in 1832, able men abroad became interested in the scientific investigation of the subject. In this country it was taken up in a far less scientific spirit. Most extravagant and incredible statements as to the results to be obtained from faradization were freely made, and although a few honest physicians endeavored to give respectability to electro-therapeutics, the majority of workers in this department were laymen, having no part or lot in the realm of science, and as devoid of conscience as of intellect. Many of these practitioners combined localized with general faradization, and some employed the latter exclusively, though with little definiteness or precision.

And yet it must be admitted, I think, that many of these empirics, by general or localized faradization, or both combined, or by methods various and inconstant, achieved successes in the treatment of disease surpassing those obtained by many physicians at the present day. Some twenty years ago I met at the bedside of a patient an old gentleman of whom I had frequently heard, and who had for years been known to very many practitioners of New York. Without possessing the slightest knowledge of anatomy or physiology, or of the principles and practice of medicine, this man had for thirty-five years followed the so-called business of an electrician, and had treated an enormous number of persons. I was amused by many of his absurdities of statement, but was thoroughly impressed by his unswerving integrity and vast experience, and I naturally desired to know more of his method and processes in a field, at that date, so little cultivated by the profession. On many occasions subsequently I carefully watched his methods of procedure, and saw him successful in desperate forms of chorea, neuralgia, and in many other forms of chronic nervous disease.

The first case that in this way fell under my observation was one of most severe and persistent nephralgia. For over five months this patient—a young man of about thirty-five—had every day suffered paroxysmal attacks of pain of the most agonizing character. He had unsuccessfully sought relief in every direction. Seven applications given by this old man secured to the patient complete and permanent relief.

A second case that impressed me strongly occurred in the person of a little girl about ten years of age, suffering from a severe form of St. Vitus's dance of eight months' standing. She had taken medicine freely, and, so far as I could judge, judiciously enough. Among other things, I found on examining one of her old prescription bottles that Fowler's solution had been taken in considerable quantity. The patient was treated in the usual stereotyped manner of this operator, and after less than a dozen applications her recovery was assured.

Here are but two of many unwritten cases that in this way were forced upon my attention, and induced me at that time to study more closely the clinical side of electro-therapeutics. Now, this man knew nothing of electro-physiology, or of kindred departments, and while he had a superficial idea of the effects of the constant current, he had never used it, but had confined himself to the use of the faradic current. So far as concerns scientific electro-therapeutics, he existed as a most remarkable example of profound ignorance and immense experience, associated with perfect honesty of intention. He never enunciated an idea; neither had he any conception of the principle on which he worked and through which he wrought cures. He was, however, so thoroughly the master of the method that he invariably used, that the truth of the saying, "that it is not so much electricity that cures as the manner of using it," never seemed so clear as when comparing his effective manipulations with the awkward slipshod movements that are only too frequently the results of careless attempts at imitation.

About this time I renewed an old acquaintance with Dr. Geo. M. Beard, who had recently come to New York and had become connected with the Demilt Dispensary. He also was more or less interested in the subject, and informed me that while still a student at Yale, he had in his own person experienced much benefit from the use of electricity in the relief of a condition of persistent indigestion and nervousness. Supplying ourselves with such apparatus as could be obtained at that date, and depending almost entirely for cases on such as could be sent for free treatment from the dispensary, we began work in a deliberate and systematic way, for the purpose of determining as far as possible the real therapeutic value of electricity. But instead of localized, we now used general electrization, and with results that were far beyond our anticipation. We found that many of the patients thus treated were not only relieved of their local symptoms, but were also improved very decidedly in their general condition. Old cases of indigestion with the usual accompanying symptoms, and a variety of disorders associated with general debility, were very appreciably relieved, and in some cases entirely or approximately cured by persistent treatment. These results and experiences we subsequently embodied in a series of five articles in the *New York Medical Record* under the title of "The Medical Use of Electricity," and the novelty of the views therein expressed and the impression they made was evidenced by the reception accorded them both here and abroad.

At the present time, when the wide therapeutic effects of electricity are so generally appreciated, it is difficult to indicate the intense degree of interest developd by the enunciation of such positive and radical statements in regard to an agent that was looked upon by scientific men only with contempt, or, at least, with indifference. It must be remembered that at that date the whole subject was a veritable *terra incognita*, and to touch it, as one worthy friend remarked to me, was to imperil one's professional reputation. Very naturally, in entering a field so untried, I was desirous of the moral support of men of character and standing in the profession. One of our most eminent surgeons, a man most kindly in nature, broad in his views, and well disposed toward myself, said to me: "It isn't worth your while—any old woman can apply electricity." Another physician, and former teacher, equally eminent in medicine and an author of great fame, prematurely exclaimed as I began to speak of the matter to him: "Oh, I cannot lend my name to any such project!" "But I do not wish your name," I replied; "I simply came to tell you what our idea is, and to ask your opinion as to the propriety of endeavoring to develop the subject of electricity in a legitimate and scientific way." He advised me to keep on in the regular path, and not to meddle with it, but let it remain where it belonged—in the keeping of charlatans.

During my medical college course I do not remember to have once heard the word electricity in connection with the treatment of disease. Medical journals seldom referred to it in any way, and of American literature upon the subject, with the exception of Garrett's ponderous and unphilosophic work, there was absolutely none. It was impossible to obtain any form of apparatus for the generation of the galvanic current, and all our earlier efforts in this direction were made with the inconstant, inconvenient, and bad-smelling voltaic pile. Electricity was known to be of value in stimulating muscular contractions, and paralysis was believed to be about the only condition for which its use was indicated.

Duchenne and Remak abroad, and after them Benedict, Schultz, Meyer, Neumann, Rosenthal, Frommhold, Eulenberg, and others, worked up the field of localized electrization, and in proportion as their knowledge was limited in regard to the whole matter, in just that proportion were they dogmatic in the assertion of their beliefs. They laid especial stress on physiologic experiments without having yet learned much about the physical effects of electricity. One preferred the galvanic and another the faradic current, and heated controversies were held as to whether the better therapeutic effects were obtained by the application of the current to the motor points or to the muscles themselves. Fierce and unreasonable controversies were carried on.

When, therefore, these articles of ours, to which reference has been made, asserted and demonstrated that electrization was something more than a mere stimulant, that it was also a tonic of very remarkable efficacy, and as such was indicated in a wide range of diseases associated with general debility and impaired nutrition, the medical press, here and elsewhere, gave to the subject the most careful consideration. In Germany everything relating to these new suggestions was reproduced and discussed, and to Professor Erb, of Heidelberg, more than to any other, is due the fact that the method by which general nutrition was best influenced was received with so much interest and appreciation.

Up to this time, as far as can be ascertained, men of science had confined themselves solely to purely localized methods of application; and it is a matter of observation that they failed to secure results equal to those of a few empirics who, in spite of their own ignorance, were in daily use of broader and more rational and effective methods. The defect of these empirics, therefore, was not in their results, which oftentimes were truly remarkable, but in the fact that their ignorance of medicine rendered it impossible for them to discriminate in their cases or in their methods, or to intelligently communicate their experience to others, or in any way make it of permanent value to science.

Our own claims in regard to this more general method of using electricity as practised by some of these empirics are: 1st. To have improved it, reduced it to a system and given it a scientific basis, and to have shown its relation to other methods of using electricity; in short, to have done for the method of general faradization what Duchenne did for localized faradization. 2d. To have interpreted its special and general effects; to have given it a name, pointing out the true rationale of the method, and the indications for its use. 3d. To have first called the attention of the profession to this method, enforcing our views by the results of personal experiments, and awakening an immediate interest in this department of therapeutics. 4th. To have discovered in our experiments with this method that electrization is a tonic of great and varied efficacy, and therefore indicated for many conditions; and to have forced this fact on the professional mind until it has become widely accepted, and has become the basis for the use of electricity in a multitude of diseases. This subject was still further developed when we issued the first edition of our *Treatise on the Medical and Surgical Uses of Electricity*, but it was not until the second edition that another important method, which we termed central galvaniza-

tion, was considered with the fulness of detail that its importance demanded. It is so thoroughly established that external applications of the galvanic current penetrate directly to and appreciably affect the brain, and furthermore, that such applications are often of immense service, that it would be unnecessary to advocate its utility were it not that authoritative names were pledged to its condemnation. I cannot attempt in this paper to consider fully the grounds of this condemnation; but a reference to some of the objections of Cyon, as put forth in his *Principles of Electro-therapeutics*, cannot fail to show their unreasonableness and to carry the conviction that the learned teacher is more theoretic than practical. Because we cannot localize the galvanic current in special portions of the brain; because we cannot perfectly explain or understand its physiological action on the centers of thought and motion, or why this action seems to be frequently adapted for the relief of many symptoms of cerebral disturbance; and finally, because we cannot uniformly predict that relief will follow the use of central galvanization in certain conditions—these considerations should be no bar to our use of the current in this way.

In a somewhat varied experience I have observed so many suggestive results follow the use of central galvanization in the psychoses, that I have but little doubt, if in our insane-asylums a systematic and patient trial of this method could be adopted, that a certain proportion of cases now regarded as hopeless would be more or less benefited. In following the views and suggestions of Apostoli, much good work has been done in America in gynecologic electro-therapeutics, but the impetus to these investigations came from abroad, and in this department we have followed rather than led.

That there has been gross exaggeration, both conscious and unconscious, as to the magic effects of electricity in the dispersion of fibroid tumors, is undeniably true. Notwithstanding all this, however, we have cause for congratulation that electricity has proved so efficient a remedy in so many of these cases. Among those who have recorded their observations and the results of their work in this department of electro-therapeutic work are Engelmann, Massey, Martin, Mundé, Grandin, Gunning, Goelet, Bigelow, Kellogg, Hutchinson, and not a few others. The revival of the use of static electricity in France some dozen years ago led to the discovery of what is now well known as the static induction current of Dr. Wm. Morton. This discovery is entirely American, and while it yet remains for us to definitely differentiate between it and the ordinary current of induction as regards therapeutic effects, it is undoubtedly a suggestion of value and widens the utility of the Holtz machine. The use of electricity in the treatment of extra-uterine pregnancy is another most important advance in electro-therapeutics that is entirely American; and were accidents of gestation of this kind an everyday affair instead of comparatively infrequent, the discovery of the great value of electricity in their treatment might well be considered one of the most important of recent therapeutic procedures.

It is unfortunately true that there are many who still decry the method and advocate the use of the knife in those early-discovered cases in which electricity is indicated.

They cannot deny that, if detected before the third month, electricity is capable of destroying the fetal life without pain or danger to the mother. But, they say, a foreign body is left, therefore the knife should be used; and this in the face of proofs innumerable that no possible harm results from the contents of the fetal sac, which become encysted and quickly absorbed. Two assertions are often made by the opponents of the electric method of treatment: 1st. That it is almost impossible to detect the condition before the third month, and that many supposed cases of extra-uterine pregnancy are not cases of pregnancy at all. 2d. That electricity is by no means sure to destroy the fetal life.

In reply to the first of these, I have this much to say: A patient comes to you with a cessation of menstruation of two or three months' standing, associated with paroxysms of pain with or without a slight show of blood. On examination you distinctly feel a slight enlargement along the line of the Fallopian tube. It may or may not be a case of tubal gestation, but you treat it with electricity, and the pain immediately ceases and the tumor quickly disappears. What could it have been? Certainly not an ordinary cyst or solid tumor, for these do not disappear in this way. The only rational conclusion is that it was an ectopic gestation—the only possible condition that would thus readily resolve itself under the electric treatment. In regard to the second objection, the difficulty has been that the faradic current is too often used to the exclusion of the galvanic. It is a great mistake to rely on the faradic current, since it is far more inefficient in its destructive properties than is the galvanic.

It possesses in equal degree neither the physical, chemic, nor physiologic effects of the galvanic current, while the mechanical effects are common to both currents. The galvanic current always kills. In the sixteen cases of extra-uterine pregnancy that have come under the personal observation and treatment of the writer, the galvanic current was exclusively used, and always with success.

CONCLUSIONS. — The progress of electro-therapeutics has been neither rapid nor uniform; it has been marked by alternations of eras of extravagant faith and activity with eras of equally extravagant distrust and neglect. Though often in advance of, and unaided by, physiology and pathology, it has been so closely dependent on the mechanical contrivances for generating and controlling the electric current that it has necessarily risen and fallen with the progress of mechanical art, and to a certain extent has shared in the fluctuations of electro-physics. Beginning with the mythic procedures of the Roman physicians with electric fishes, it had long slumbered in the forgetfulness of ages, when it was revived in the eighteenth century by the experiments with frictional electricity and the great discovery of Galvani. The interest thus aroused by galvanism and the invention of the voltaic pile rose to a height of enthusiasm that led to the belief that the problem of therapeutics was solved forever, until from repeated failures and disappointments there ensued a reaction of indifference that for many years was only disturbed by the birth of electro-puncture and by experiments in electro-surgery.

The discovery of induction and the modern improvements in galvanic batteries have inaugurated a new revival of electro-therapeutics in which the enthusiasm of the profession, rendered skeptical by past history, but now convinced by unequivocal demonstration, has been slowly and reluctantly enlisted. This last revival, it is safe to predict, will be as much more extensive and permanent than any of its predecessors as its growth has been more gradual and scientific. Thus, after more than a century of experiment and failure, electro-therapeutics is beginning to realize something of the hopes of its early supporters. The tardy fulfilment of the promises of its youth are due not so much to the prejudices of men of science as to the necessary mechanical difficulties in the way of its employment, and to a want of knowledge of the indications for its use and the method of making the applications. The prejudice of which so much has been said was the natural result of the many failures of electricity, and of the fact that, like many other excellent agents, it was for a time almost exclusively in the hands of charlatans.

The history of electro-therapeutics, with its varied alternations of failure and success and its ultimate triumph, may not inaptly be compared with the incoming of the tide upon the shore, where, although each successive wave apparently recedes as far as it advances, the level of the water is ever gradually rising with a force at once sure and irresistible.

OCCLUSION OF BOTH COMMON ILIAC ARTERIES; GANGRENE; DEATH.

BY HUGH B. MEREDITH, M.D.,

FIRST ASSISTANT PHYSICIAN TO THE STATE HOSPITAL FOR THE INSANE, DANVILLE, PENNSYLVANIA.

IN offering the following report, no new light is thrown upon the etiology, pathology, or treatment of embolism and resultant thrombosis of the larger vessels; but symmetrical gangrene resulting from embolism of the aorta at the iliac bifurcation is of such infrequent occurrence as to be worthy of notice. Rosenstein[1] says that "clots in one or more large arteries of the lower extremity are fortunately of rare occurrence," and alludes to one case that came under his observation, in which mortification of the whole leg developed. Probably the most frequent point of lodgment of an embolus in the lower extremity is at the bifurcation of the popliteal artery, resulting in dry gangrene of the leg that may extend to within a few inches of the knee. A simultaneous occlusion of the arteries at this point in both limbs is less likely to occur, but is within the bounds of possibility. The following case is one in point:

E. C., forty-eight years old; a female; married, having borne two children; a school-teacher, in moderate circumstances; was admitted to the State Hospital for the Insane, November 20, 1888, suffering from melancholia of about three weeks' duration. There were no known hereditary tendencies, her insanity being attributed to excessive mental work and financial losses.

She was of medium size, fairly proportioned, and somewhat emaciated, with a sallow complexion. Her tongue was coated and her bowels were torpid. The pulse was 84, irregular and intermittent; a mitral regurgitant murmur was heard. There was a history of palpitation and of vertigo. Menstruation had been absent for some time. A history of rheumatism could not be elicited. There was delusional melancholia of a religious type.

As the physical condition improved, the mental condition likewise improved, and at the expiration of four months the woman had so far regained mental health as to be considered convalescent. There remained, however, frequent headaches, accompanied with vertigo, disturbance of digestion, vomiting, diarrhea alternating with constipation, and indefinite subjective symptoms mainly attributable to faulty heart-action. Menstruation was re-established. The patient gained flesh, but remained pale and anemic.

On the morning of April 19, 1889, when called for breakfast, the woman was found helpless upon the floor, having apparently risen as usual to dress. When seen a half-hour subsequently, consciousness was preserved, though the patient was confused and restless, the face flushed and expressive of great

[1] Ziemssen's Encyclopedia of the Practice of Medicine, vol. vi, p. 124.

anxiety. Aphasia was not observed; the tongue was deflected to the right; the pupils were normal; sensibility and motility of the left arm, as compared with the right, were much impaired; the woman was, however, able to execute the coarser movements. There was complete paraplegia; the lower extremities were cold and marked up to the knees by a death-like pallor. The left leg was anesthetic to the level of the knee; the right leg to the foot. The pulse was 60, very weak and irregular. Prostration was decided. Frothing at the mouth and a slight convulsive movement limited to the upper extremity had been observed.

Occlusion of the abdominal aorta at its bifurcation, probably by an embolus, a small embolus also being lodged in the brain, was diagnosticated. Spiritus frumenti and ammonium carbonate were given every two hours until reaction was established; external heat was applied to the lower extremities. By eight o'clock in the evening the woman had rallied from the shock and felt better; she ate a slight dinner; the bowels moved naturally; the urine was dark and heavy from admixture with blood; the right pupil was dilated; the pulse was increased in frequency and tension.

On April 20, power in the upper extremities had been partially regained. The lower extremities assumed a dark, mottled appearance, and remained cold and paralyzed.

On May 3, lines of demarcation appeared to be forming near the middle of the left leg and at the junction of the middle and lower thirds of the right leg, as revealed more particularly by differences of temperature. The distal portion was cold, black, or mottled with pinkish points and blotches, which were somewhat warmer. Above, the limbs were swollen and painful, but the hyperesthesia was more intense in the gangrenous parts, the pain being likened to the "boring of worms," and being much intensified by the weight and warmth of the bedding.

The appetite was poor, the tongue dry and brown, and the pulse 68, small and weak. The dejecta were passed incontinently. Insomnia was marked. Speech was incoherent and delusional.

On May 4, there occurred a sudden extension of the gangrenous process on both limbs to the knees, and on the right posteriorly to the sacral region, where there was a similar process in an area several inches in diameter. Large bullæ formed on the calves and ruptured, discharging bloody serum and leaving excoriated patches. The pulse was 72, weak and intermittent. The patient gradually failed, and died May 20th, four weeks from the beginning of the attack. The days preceding death were marked by moderate elevation of temperature, frequency of pulse, diarrhea, and paralysis of the sphincters.

At the autopsy, twenty-four hours after death, the gangrene was found to extend on the left side to the knee-joint, above which the limb was merely slightly edematous, with engorgement of the superficial vessels. On the right side the gangrenous condition extended along the posterior aspect of the thigh, joining a similar patch about six inches square over the sacrum. The anterior aspect of the thigh was edematous. At the upper inner margin of the right popliteal space there was a large cavity containing several ounces of clear, oily fluid, much resembling olive oil, and offensive in odor, evidently a collection of liquefied fat.

The heart was evidently enlarged by dilatation of the auricles, the walls of which were thinned, and their cavities filled with ante-mortem (terminal) clots. The left auricle was distended with a clot that extended through the pulmonary veins into their smaller divisions in the lungs; within the auricle the center of the clot was broken down into a cheesy mass, offensive in odor, and resembling the contents of a pus-cavity. The right ventricle contained small, adherent clots, entangled in the chordæ tendineæ. The left ventricle was empty and contracted, the heart evidently stopping in systole. The aorta contained a white clot, extending from the valve to beyond the arch. The mitral valve was thickened, the seat of plates and nodules of calcareous matter, and partly bound down; the mitral ring was rigid, and contracted to about one-third its normal diameter, barely admitting the extremity of the little finger, and giving evidence of decided insufficiency and stenosis. The remaining valves and orifices appeared normal. The heart was soft and pale; the walls of the ventricles were apparently unchanged. There was no degeneration of the arteries. Spleen and liver were engorged.

The right kidney was about one-half of the normal size, much nodulated, irregular in contour, and of a dark-gray or slate color. The capsule was moderately adherent. Section revealed numerous old hemorrhagic infarctions; the cortical substance was generally thinned and wanting in the situation of the cicatrices; in several places the base of a pyramid was apparently in immediate contact with capsule. The left kidney, rather larger than the right, presented the same general appearance, though in a minor degree. One pyramid was of a yellowish color, and had evidently undergone fatty degeneration. The abdominal aorta was found to be normal as far as its bifurcation, beyond which the walls of the arteries were black in color, showing advanced gangrene, and their caliber was obliterated by firmly-clotted and partly-organized blood. Beyond the division of the common iliacs the contents of the vessels were firmly organized, the vessels being almost converted into fibrinous cords; on the proximal side of the iliac bifurcation the contents were less highly organized, but yet firmly coagulated. The firmness of the clot was more pronounced in the right common iliac and its branches than in the left. The iliac muscles were dark-colored and evidently becoming gangrenous.

The brain was not examined, for want of permission.

The apparent cause of the occlusion of the arteries in the case reported, based upon the sudden inception, the completeness, the bilateral character, the gangrenous condition of the common iliac arteries, associated with extensive valvular disease, seems to have been the lodgment of some detritus from the

heart at the bifurcation of the abdominal aorta, where by fibrinous accretions the embolus gained sufficient size to suddenly block the main divisions of the aorta, probably at the bifurcation of the common iliacs. The only modifying fact was the fairly well-nourished condition of the anterior surface of each thigh, which would seem to have been improbable were the profunda arteries implicated, the collateral circulation through the internal mammary or other accessory vessels being scarcely sufficient to maintain the requisite blood-supply.

The numerous infarcts of the kidneys would indicate the repeated detachment of cardiac emboli, so that possibly there was a simultaneous lodgment of fragments in the two femorals rather than at the aortic division. The limitation of the gangrene to the legs, as seen in the imperfect attempt at a line of demarcation, the subsequent sudden extension of the process up the thighs, and the gradually increasing degree of organization of the clot from the distal to the proximal extremity of the vessels, would favor this latter conclusion—stasis of the current favoring the formation of a thrombus between the original point of occlusion and the abdominal aorta, the completion of its formation being manifested by the extension of the gangrene.

One source of gangrene of the lower extremity that may extend to within a few inches of the knee, as already stated, is embolism of the popliteal artery at or just above its bifurcation. Another potent cause, as seen in senile gangrene, is slowing of the blood-current as a result of partial obliteration of the lumen of the popliteal arteries by atheromatous degeneration.[1] "The arrest of the circulation, from being partial may suddenly become perfect," in consequence of the formation of a thrombus, and then the gangrene will in a few days reach the knees, subsequently becoming moist. In neither the case reported nor in the following case was there a tendency to obliteration of the main vessels of the pelvis and lower extremity above the primary lesion, and this too, notwithstanding the existence of favoring circumstances. The report of the following case has been kindly furnished by Dr. C. B. Mayberry, in whose wards it occurred:

G. C., a male, seventy-four years old, was admitted to the State Hospital for the Insane November 21, 1889. He was of average height, of slender build, emaciated, and in feeble bodily condition; the pulse was weak and irregular. The respirations were 21; the temperature was 98°. A mitral systolic murmur was heard at the apex of the heart. The tongue was coated; the appetite was impaired; little food was taken in consequence of delusions of acute melancholia.

[1] Ashhurst: International Encyclopedia of Surgery, vol ii, p. 301.

April 17, 1890. Without any change in the general health, gangrene of the left foot developed, which gradually extended up the leg. The foot became cold, dry, and shrivelled, with patches of ulceration and slow sloughing, and with decided constitutional disturbance.

20*th*. The process had gradually extended, and the patient was slowly failing. There was no perceptible pulsation in the arteries of the leg or foot. The pulse was 120; the respirations 25; the evening temperature was 103°. Amputation was considered, but not deemed advisable, owing to the weak condition of the patient. Death took place at 8.45 P.M. on April 25th.

At the post-mortem examination of the foot, dry gangrene was found extending half-way to the knee. The popliteal artery in its upper part was found much diminished in caliber, one side of its wall being much thicker than the other, in consequence of the organization of an old thrombus. The crescentic-shaped lumen gradually became less marked and finally disappeared in the lower part of the artery, thus cutting off all circulation to the leg. An attempt at collateral circulation had been made by enlargement of the arteries about the joint. No further examination was made.

The feeble condition of this patient, the form of mental disorder, and the existence of organic disease of heart, would seem to have been favorable to an extension upward of the thrombotic process, so as to involve at least the entire femoral artery; but in this case, as in others, the gangrene was comparatively limited in extent.

Moore,[1] in describing symmetrical gangrene, says: "It may also be the result of embolism of the aorta at the iliac bifurcation—a cause which can be easily appreciated." If partial gangrene, as he describes it, can be produced by so potent a cause, even more extensive partial gangrene might have been expected to result, as in the case of E. C.; hence it is not unreasonable to refer the initial point of occlusion to the common iliacs.

Embolism of one branch of the abdominal aorta, while infrequent, is probably not so rare as embolism of both branches. The causation and train of symptoms are necessarily the same. The following case is also taken from the male records:

E. J., a male, sixty-three years old, was admitted to the State Hospital for the Insane February 22, 1884. He was tall, slender, much emaciated, and in poor physical health. The pulse was 96, small and regular. The appetite was capricious, owing to delusions respecting food. The man was subject to chronic diarrhea. On admission he was wildly incoherent, noisy, suspicious and afraid of others, sleepless, destructive, and uncleanly in his habits. He presented delusions mainly of a depressed nature, but showing the exaltation of manner usual in mania. In May, 1888, he had a mild attack of

[1] Loc. cit., p. 305.

pneumonia, from which he did not recover for many weeks. During May, 1890, he had a slight attack of facial erysipelas.

About 11 A.M., January 30, 1891, it was noticed that the patient was unable to use the right lower extremity, which was cold, and very soon presented a mottled appearance. Sensibility and motility were lost. The femoral artery was pulseless. Consciousness was preserved, the mental condition being unchanged. The entire limb and lateral half of the scrotum were involved, showing occlusion of the main artery, probably at the division of the abdominal aorta. No change occurred in his condition until 6.30 A.M., January 31st, when he suddenly expired.

There was no history of organic disease of the heart. On the contrary, the man was considered phthisical, no definite information being obtainable on physical examination, owing to the constant excitement under which he labored.

At the autopsy, thirty hours after death, the right pelvic region, the right lateral half of the scrotum, and the entire right thigh presented a dark, mottled appearance.

The right heart was normal; the left was enlarged. The cavities contained ante-mortem clots. The mitral valve was normal. The aortic leaflets were the seat of calcareous plates; the roughening of the surface and the presence of small vegetations afforded evidence of old endocarditis, the pathological condition permitting decided regurgitation and causing some obstruction. Atheromatous degeneration prevailed throughout the arterial system. The lumen of the colon was narrowed in many places, as a result of chronic colitis. The right common iliac artery was entirely closed by a blood-clot of firm consistence. Judging from the character of the occluding body, it was thought that the point of lodgment of the detritus or vegetation from the heart was at the division of the common iliac, where the thrombus that formed attained sufficient size to plug the vessels upon the distal side, and subsequently upon the proximal side as well, thus obliterating the lumen of the artery from its commencement at the aorta, and depriving the entire right half of the pelvis and the right lower extremity of blood. The brain was not examined.

The cause of the rapidly fatal termination may have been heart-failure, due to a sudden increase of resistance in the blood-current thrown upon a badly impaired organ, though the same increase of resistance may have given rise to an apoplexy, a plausible theory in view of the weakened condition of the arterial vessels consequent upon atheromatous degeneration.

Had not this case pursued so rapid a course as a result of a secondary accident, without doubt it would have eventuated in moist gangrene of the entire limb, and have terminated by septic poisoning.

In the cases reported the form of insanity was melancholia, a disease characterized by a weak and sluggish circulation, and which, when associated with grave, organic heart-lesions, or a more frequently occurring degeneration of the coats of the vessels to which the insane are peculiarly liable, presents sufficiently potent factors for the development of the accident.

The frequency of these cases among a comparatively small number is suggestive of a marked predisposition of the insane to embolic occlusion of the arteries, an inference even more patent when we include in the category localized softenings dependent upon embolism of the cerebral vessels.

ACTINOMYCOSIS.

BY WM. P. McGOVERN, M.D.,
OF CBOARBURG, WIS.

THE number of cases of actinomycosis seen and published has increased every year since the appearance of Ponfick's first contribution to the *Berliner klinische Wochenschrift* in 1879, but there has not been much added to our knowledge of its nature, cause, and treatment. The greater number of cases have been reported by German authors, and as late as 1885 W. T. Councilman, in describing this disease, said that no case of its occurence in man had been recorded in the United States. In England the first case of removal of the growth has been reported during the current year. That actinomycosis was met with as frequently previously to 1879 as since, no one will question, and that it occurs as frequently elsewere as in Germany is beyond doubt.

The case related in this paper, and two cases treated by Dr. N. Senn, and fully described in his *Principles of Surgery*, have originated within a radius of thirty miles during the last five years. Dr. J. B. Murphy, of Chicago, has treated five cases of actinomycosis, his first case being the first recognized in man in the United States.

Actinomycosis is a parasitic disease caused by a fungus that was at first classed among the cladothrix variety of algæ, and later was placed among the leptothrix group, and was viewed as a metamorphosed form of the leptothrix buccalis. The fungus is supposed to be found in nature, growing upon certain cereals as barley, rye, and corn; certain it is that a metamorphosis takes place in this fungus after entering the human body. The arthrosporous schizomycetes are noted for pleomorphism, and especially is this true of the cladotricheæ, which, in one and the same life-history, present the forms of cocci, bacteria, bacilli, leptothrix-filaments, spirilla, and vibriones; they may be parasitic to a higher organism and assume new and different forms. Pleomorphism may account for the confusion that seems to exist in regard to this fungus, as to whether

it is a cladothrix, leptothrix, hyphomycete, or some "higher form of bacteria."

The actinomyces-body or spherule is about the size of a millet-seed and usually whitish-yellow in color, and is not found floating in true pus, but in a gruel-like matter which is perfectly odorless, except when contaminated with some extraneous matter. We know nothing of its manner of emigration in the human body, but about its mode of entrance we have the discovery of Israël and Pratzsch of these spherules in the cavities of carious teeth. In my case there was a spherule in the cavity of a carious tooth, and two within an abscess-sac attached to one root.

Actinomycosis has been found in almost every organ and portion of the body, but in the greater number of cases the disease has been located in the neighborhood of the mouth. Carious teeth, lesions of the mucous membranes of the mouth, respiratory tract, and alimentary canal, have allowed this parasite to enter, as also have lesions of the integument, giving rise to a primary actinomycosis of the skin. It has been discovered in the heart, lungs, liver, kidneys, brain, bladder, prostate gland (?), peritoneum, pleura, and spleen—organs and membranes to which it gained entrance through the blood.

The disease is an exquisitely chronic one (at no time is there true systemic infection) characterized by a granulation-tissue proliferation. Unlike the true systemic infectious diseases, tuberculosis and syphilis, the lymphatic glands are not involved, except by simultaneous suppuration induced by the specific excitant bacteria of suppuration.

The prognosis is very unfavorable. When found in certain organs, as the heart, liver, spleen, brain, and kidneys, the disease is considered fatal; but when located on the face or neck, or as a primary actinomycosis of the skin, the prognosis is most favorable.

Up to the present time, and with varying results, the treatment of actinomycosis has been purely surgical. In many of the cases operated upon the disease has recurred on account of failure to remove all of the diseased tissue. The only treatment with drugs—without resorting to operative procedure—is that first used by Dr. Köttnitz[1] in four cases of actinomycosis of the cheek and neck; all four recovered. The drug used was the nitrate of silver stick, and the diseased tissues were cauterized freely and frequently until all traces of the disease had disappeared. The first case in which this treatment was used was one of reappearance after several attempts at removal by operation. When the disease is situated in certain organs of the body in which surgical treatment is not applicable, nitrate of silver would also be inadmissible. The following case will illustrate this method of treatment and its good result.

The patient, J. H., was first seen August 30, 1891. Examination revealed a swelling occupying the angle of the lower jaw on the right side. This swelling, the size of half a lemon, was dense to the touch, gave no fluctuation, and was surrounded by an ill defined mass of infiltrated tissues, extending in all directions, but more particularly downward and backward over the sterno-cleido mastoid muscle. The skin was red over the central portion of the tumor, but there was no tenderness on pressure. The mouth and teeth showed evidence of lack of attention, and the last molar on the right side was carious, but had not ached.

On July 27, 1891, the patient first noticed a bean-like swelling opposite the angle of the jaw. This steadily increased to its present size, without becoming painful, tender on pressure, or giving rise to fever. The patient's condition was good, though he had of late lost considerable in weight. No positive diagnosis being made, expectant treatment was adopted.

On September 7th, a soft spot was found at the center of the tumor. Incision evacuated about one teaspoonful of a gruel-like matter, containing numerous yellowish-white bodies. A diagnosis of actinomycosis was then made, which was soon confirmed by microscopic examination.

The patient was seen daily either by myself or by my associate, Dr. E. R. Moras, and the abscess-like cavity was syringed out, with either a solution of tincture of iodine in alcohol, or a 1 : 1000 solution of bichloride of mercury, or a 5 per cent. solution of carbolic acid, and packed with gauze. I extracted the carious tooth on the 16th. Two actinomyces-bodies were found on one root, and one other was lodged in its cavity.

On September 24th, the cavity in the cheek, and as much of the surrounding indurated tissues as could be reached, were cauterized with the nitrate of silver stick. When the patient returned on the 27th, the change was surprising; the cavity was practically obliterated, and already the induration was markedly less. A mass of spongy granulation-tissue protruded from the wound, and by pressure a slight amount of the characteristic actinomycotic fluid could still be obtained. The cauterizations were repeated every third or fourth day. The improvement was unexpectedly rapid and pronounced. The last application was made on November 8th; on November 15th the patient was discharged cured, only a small scar remaining.

The patient has been seen several times since, and nothing suspicious has as yet developed.

Dr. Köttnitz states that in all of his cases there were defective teeth on the affected side, and all the patients had neglected the proper care of their mouth and teeth. In my case this was also true, and the carious tooth was undoubtedly the avenue through which the parasite gained entrance into the tissues. This fact suggests scrupulous cleanli-

[1] Deutsche med. Wochenschr., September 3, 1891.

ness of the mouth and teeth as the chief prophylactic measure.

A sufficient length of time has not elapsed to say that the disease will not recur, but up to the present time (December 14, 1891) there has been no sign of recurrence. The result obtained from this treatment has been such as to warrant a further trial in cases of actinomycosis in which the disease is situated in portions of the body accessible to cauterization.

"The favorable action of the remedy is probably to be found in a peculiar susceptibility of the actinomyces to the action of certain drug-reagents to which probably the nitrate of silver belongs, or the cauterization gives rise to an active inflammation with all its consequences, which is of importance in fighting this foreign element." (Köttnitz.)

In the case reported there was no sign of active inflammation, except when healthy, non-infiltrated tissues were cauterized; pain was comparatively slight, and the cauterized reticulated granular mass was usually thrown off on the second day after the application. The nitrate of silver seems to have some selective action upon the fungus and the granulation-tissues within which it grows, as the normal tissues were but seldom attacked, even when the caustic was used very freely.

There is no evidence of the transmission of actinomycosis from man to man, or from animal to man; and as the disease is almost always local, the danger of infection from the meat of diseased animals is not very great, and if the precaution of thorough cooking is taken, as in trichina-infected meats, the danger is *nil.*

CLINICAL MEMORANDA.

THE FUNCTION OF THE SEMICIRCULAR CANALS.

By E. D. SPEAR, M.D.,

AURAL SURGEON TO OUT-PATIENT DEPARTMENT BOSTON CITY HOSPITAL, AND TO THE MASSACHUSETTS CHARITABLE EYE AND EAR INFIRMARY.

HÖGYES[1] believes that the semicircular canals of the ear, with the vestibular branch of the auditory nerve, are a peculiar end-apparatus regulating the movement of the muscles of the eye, and probably of the other muscles of the body, for the maintenance of equilibrium.

In order to put this to a test, and decide whether there is to be found any direct (or indirect) connection between the organs to which I apply the name peripheral space-organ (namely, the semicircular canals of the ear) and the muscles of the eye, I chose certain cases from among my patients who made complaint of dizziness, or whose gait in walking showed disturbances of equilibrium, and asked my friend, Dr. H. B. Chandler, of Boston, to examine their ocular muscles.

The result of our mutual investigations caused us to come to the definite conclusion that in regard to the sixth (abducens) nerve there was a most intimate connection with the vestibular branch of the auditory nerve. All dizzy patients had exophoria of varying degree dependent upon the amount of intensity of the peripheral irritation.

Without entering into the details of the cases examined, or touching upon other important and interesting questions, I transcribe enough data to encourage one to continue these interesting observations, and I suggest for consideration two typical cases recently observed.

First, a strong, able-bodied man, exposed to inclement weather, and, in consequence of repeated wettings, developing a post-nasal hypertrophy of the right turbinated body, presented himself for relief of intense pain in the corresponding ear. He was found to have a severe form of otitis media acuta, with a small perforation of the drum-membrane, and oozing of the serum from the engorged bloodvessels of the tympanum. The patient was in great agony from the pain in the ear and head, was very unsteady in his gait, staggering forward and to the right; he complained of great dizziness, and was at times nauseated. He also appeared to have a complete ophthalmoplegia interna on the right side, due to what at first seemed a paresis of the internus muscle. The demonstration of this state of the ocular muscles needed no prism, because the divergent eye could not be brought to the median line even when its fellow was strongly converged. There was, necessarily, diplopia.

In order that this highly interesting and deeply instructive case might not lose its effect upon its observers—among whom was my colleague and friend, Dr. C. J. Blake, of Boston—I avoided using any means of treatment which might not be clearly understood; and, as the exigency demanded immediate relief for the very severe symptoms, I used the simplest means at hand. A large tampon of absorbent cotton dipped into a 4 per cent. solution of cocaine hydrochlorate was carried deeply into the right nasal fossa. This was allowed to remain in position ten minutes, was then removed, and nothing more was done. At once, upon the removal of the cotton, the patient converged his eyes normally, could walk in a straight line, had complete relief from pain, and from that hour became convalescent.

It appeared clear that we had here a closed Eustachian tube, a middle ear acutely inflamed and filled with fluid pressing upon the oval window, and through it upon the ampullar enlargement of the horizontal semicircular canal. Irritation was thus probably transferred through the vestibular branch of the auditory nerve to the space-center, and through it to the terminal fibers of the sixth nerve, causing a stimulation of the muscle supplied by it, and bringing about the divergence simulating a paresis.

Dr. Myles Standish, an oculist of this city, kindly sent me a patient afflicted with dizziness. He came wearing strong prisms that fully corrected the divergence and removed the double vision, but did not relieve the dizziness or the titubation. I found great swelling of the right turbinated body, a closed Eustachian tube, depressed cicatricial membrana tympani, with fair hearing. These were results of past suppurative inflammation of

[1] Pflüger: Archiv f. Physiologie, Bd. xxvi. The Pathology of Ophthalmoplegia, by W. J. Collins, M.S., M.D., B.Sc. Lond., F.R.C.S. Eng. Amer. Journ. Med. Sci., November, 1891.

the middle ear, with restoration of the normal functions of the ear upon recovery, but not with an entirely normal condition of the parts of the ear concerned in protecting the labyrinth from undue pressure (capsular ligaments and muscles of ossicles). After local treatment of the middle ear and nose, the eye-symptoms improved, and after several applications the patient voluntarily laid aside the prisms because, as he said, they made him see double.

POISONING FROM HOMATROPINE USED IN THE EXAMINATION OF REFRACTION.

BY THOMAS R. PORLEY, M.D.,
SURGEON NEW AMSTERDAM EYE AND EAR HOSPITAL; PROFESSOR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC.

ALTHOUGH the occurrence of toxic symptoms from the frequent use of a strong solution of sulphate of atropine in the eyes has frequently been observed, I am not aware of any such effect having been produced by the use of homatropine. I have, therefore, thought it worth while to report the following case, in which the use of homatropine for the purpose of paralyzing the accommodation was followed by alarming symptoms of poisoning.

A. L., seven years old, was brought to me for examination of her eyes August 26, 1891.

$$V = \frac{20}{XXX} \text{ in both eyes, and with } + 1 \text{ D. } \frac{20}{XX}.$$

The ophthalmoscope, however, showed more H., and a 2 per cent. solution of homatropine was ordered to be put in the eyes every fifteen minutes for an hour, and the child to be brought again the next day. The day following, the drops having been used as directed, the eyes were again examined. The pupils were dilated *ad maximum* and there was complete paralysis of accommodation. H. now = 2 D. $V = \frac{20}{XX}$. A glass of + 2 D. was ordered, and the child directed to return in a week or so later.

The patient was in my office for an hour, but up to that time no effect of the homatropine other than that produced upon the eye was observed. On September 4th the child was again brought to me by her parents, who gave the following account of her behavior soon after leaving my house: On the way home she became very restless and nervous, her face was flushed a deep scarlet, and both the mind and senses were very much affected. Her ideas, which were very rapid and connected at first, became incoherent and extravagant, and she saw many imaginary objects. By the time they had reached their home her gait was staggering, the hallucinations more marked and constant and accompanied by mild delirium. Her parents, now decidedly alarmed, sent for their family physician, who made a diagnosis of belladonna-poisoning, and under the influence of some remedy given by him (probably some preparation of opium) there was an amelioration of the symptoms, with a renewed tendency to delirium and delusions. however, toward night. The following morning she was much better, but all that day was very nervous and displayed a tendency to the return of the hallucinations; and it was several days more before she had entirely recovered her usual health.

The prescription was compounded from Merck's preparation by a very careful and reliable druggist, who has kindly made for me a computation of the amount of homatropine contained in each drop of the solution. From Barnes's standard eye-dropper each drop of the solution equalled $\frac{1}{104}$ grain. From Barnes's standard medicine-dropper each drop equalled $\frac{1}{80}$ grain. The latter was most likely employed, since it is the one commonly in use. If we now take into account the number of instillations made in both eyes during the course of the hour—eight in all—we shall have as a result $\frac{2}{15}$ grain of homatropine contained in the amount of the solution employed.

It would be difficult, if not impossible, to ascertain the amount of the drug absorbed either directly or by the entrance of some of the solution into the throat through the tear-passages.

Whether a 2 per cent. solution is a stronger one than is usually employed I do not know. It is, however, the strength that I commonly use, and this is the first instance in which any disagreeable symptoms have ensued. The experience afforded by this case shows, however, that poisoning may result from the use of homatropine, and should lead to greater caution in its employment. I would suggest as a precautionary measure that in all cases in which a strong solution of homatropine is used, pressure should be made over the lachrymal sac for a few seconds after each instillation in the eye, to prevent the solution entering the throat by this channel.

MULTIPLE SARCOMA.

BY S. D. SWOPE, M.D.,
OF MARION, KY.

ON February 1st, I was consulted by S. P., a colored girl nineteen years of age, unmarried, living in the country in a healthy locality. She is the mother of one child six months old, which, to all appearances, is in good health. Her parents were healthy, had reared a large family, and there was no history of syphilis, tuberculosis, or carcinoma in the family. The patient was of medium height, well nourished, and intelligent. At the time of her first visit she was suffering from a tumor, about the size of a walnut, hard and tense, irregular or nodulated in form, with slight diminution of pigmentation over its surface, located on the ulnar border of the palmar surface of the left hand over the abductor minimi digiti. It was supposed to be caused by rubbing on the washboard. The tumor had first been noticed two weeks previously, attention having been first attracted to it by pain; since that time it has grown to its present size. I suspected sarcoma, but from the age of the patient and the history I thought I might possibly have to do with some deep-seated inflammation, and directed the application of warm fomentations and an early report to me. There was at this time no enlargement of the glands of the arm or of the axilla.

Ten days later I saw the patient again, and found the tumor much enlarged, about the size of a hen's egg, tense, hard, nodulated, and very painful. There was still no enlargement of the axillary glands. The patient had an anxious expression, and had lost much flesh. The temperature was normal; there was inability to sleep on account of the pain, which was constant and

gnawing. I gave morphine to insure rest, and advised immediate amputation of the hand, or as much of the same as I deemed necessary after examination under chloroform. Operation was refused. Eight days later I was allowed to operate, the pain having become almost unbearable, even under large doses of morphine. The axillary glands were not enlarged at this time. With the assistance of two medical friends the patient was anesthetized, when, on examination, the disease was found to have extended to such an extent that an attempt to save any part of the hand was deemed inadvisable. After applying an Esmarch bandage, the tumor was incised, and was found to be composed of an aggregation of nodules, with broken-down tissue disseminated throughout, the disease penetrating to deeper muscles and fascia. The arm was amputated at the junction of the middle and lower thirds of the forearm. The patient reacted nicely, and did unusually well until the ninth day, at which time she was sitting up, free from pain in the stump, with good appetite; but she complained of pain in the left intercostal region. There was no cough, but the pain was increased by deep inspirations. Ten days later (nineteen days after the amputation) I removed all dressings from the stump, found it completely healed, and apparently healthy in condition, the boric acid dusted on after amputation coming away dry, and the catgut ligatures and sutures having been absorbed. The patient now complained very much of pain in the chest, the axillary glands were enlarged, but there was no evidence of tumors about the chest.

Death occurred on May 1st, great dyspnea having existed during the last two weeks of life. The body, viewed post-mortem, was much emaciated. Three axillary tumors, as large as walnuts, were found, and some twenty five or thirty nodules were seated over the chest, ranging in size from that of a walnut to the smallest. They were hard and tense, and attached to the skin. A tumor as large as a filbert had sprung up on the ulnar side of the stump. No further dissection was allowed, and no microscopic examination was made.

I was especially impressed with two features of this case: the age of the patient, and the rapidity of the recurrence of the disease after amputation of the limb.

VOLVULUS FROM VIOLENT EXERCISE; LAPAROTOMY; DEATH.

BY E. V. PENNINGTON, M.D.,
OF WHITESBURG, TENN.

MISS M., eighteen years old, was seized with severe abdominal pain at three o'clock in the morning of April 9, 1891, after having turned somersaults upon a bed in the yard the previous evening. The usual means failed to relieve the pain; nor did purgatives succeed in overcoming the obstinate constipation that existed. The stomach was non-retentive. Mechanical obstruction of the bowel, dependent upon intussusception, was suspected. Ordinary treatment not availing, I was consulted for a surgical opinion. The abdomen had become tympanitic, and was sensitive to manipulation. An anesthetic was administered, and, after careful examination, I concluded that we had to deal with an intestinal twist located near the ileo-cecal valve. I placed the patient in the most favorable position and used copious injections of warm water *per rectum*, conjoined with manipulation, but without affording relief. I then stated that surgical interference was necessary. Upon consultation with the attending physicians, however, it was agreed to defer the operation for thirty-six hours.

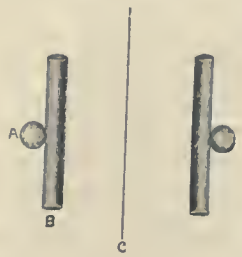
The condition of the patient not improving, the operation was finally undertaken. Dr. S. L. Pennington, Dr. King, and others assisted. An incision about four and a half inches in length was made through the linea alba. After tracing a considerable portion of the small intestine, I found the seat of trouble located in its lower portion, which was twisted upon itself, totally obliterating the lumen of the alimentary tube. Hard masses of feces were lodged against the obstruction. I corrected the trouble, washed out the abdominal cavity with an antiseptic solution, provided for drainage, and closed the wound. The patient was so weak before the operation that we feared heart-failure. By great care, however, the operation was brought to a successful termination. Eight hours later the heart began to fail, and in spite of all stimulation death took place.

The lesson of this case is the unwisdom of operative delay when urgent symptoms exist. My regret is that we did not operate while the patient had strength to bear the operation.

DESCRIPTION OF A NEW SUTURE.

BY ALEXANDER FULTON, M.D.,
OF PHILADELPHIA.

ROUND pieces of amber, about one-sixth of an inch in diameter, of various lengths, are used, perforated as required. Lead, glass, or any material that can be kept thoroughly aseptic may be used. Fine wire (silver preferred), after immersion in carbolized water, is run through the lips of the wound about half an inch from the edge when deep suture is desired, and one-third of an inch when more superficial suture is wanted. It is then put through the bar and clamped with a perforated shot. The line C represents the approximated lips of



the wound. The lips of the wound are thus by traction brought in perfect apposition. This method is especially adapted for wounds of the forehead, where there is so much tension. It always gives a neat result. I have seen every other form of suture cut through and leave the wound gaping. Sometimes the twisted suture so strangulates the tissues as to cause the part to slough off and leave an ugly scar.

Cremation.—The Japanese, who, in imitation of European nations, recently adopted the custom of burying, have returned to their original custom of burning the dead.

MEDICAL PROGRESS.

Successful Resection of Gangrenous Bowel for Incarcerated Inguinal Hernia.—STERN (*Berliner klin. Wochenschr.*, No. 41, p. 1011) has recorded the case of a woman, sixty years old, who came under observation after having presented, for a week, symptoms of intestinal obstruction, dependent upon an incarcerated inguinal hernia. An incision over the most prominent portion of the swelling in the right inguinal region confirmed the diagnosis and revealed the existence of peri-hernial suppuration. The incarcerated bowel was found gangrenous and perforated. Most careful antiseptic precautions being observed, the incarceration was relieved. The healthy intestine, on either side of the gangrenous area, was firmly grasped by an assistant and a section of bowel, about two inches long, was removed. The free margins of the remaining intestine were approximated by means of Lembert sutures, the first suture being applied at the point furthest from the mesentery, the distance being progressively halved with each succeeding suture. After satisfactory approximation, the wound was closed and dressed. The subsequent course of the case was surprisingly uncomplicated. Twenty-five days after the operation the patient was able to resume her household duties.

Ingravescent Cerebral Thrombosis and Hemorrhage during Pregnancy and Parturition.—HORROCKS (*Transactions of the Obstetrical Society of London*, 1891, xxxiii, 3, p. 201) has recorded the case of a deutipara, twenty-eight years old, who in the last month of pregnancy developed drowsiness, with rectal and vesical incontinence. The pupils were equal. There were no evidences of palsy. The urine contained neither albumin nor sugar. The heart-sounds were normal. The woman was delivered of a living child, but consciousness remained obscured. She constantly moved the right arm and leg, but the left leg was motionless and flaccid; the left arm was slightly moved. The knee-jerks were preserved and equal. The left pupil became larger than the right, though both were small. There was no apparent disturbance of respiration. After death, the veins of Galen, the right temporo-sphenoidal vein, and other cerebral veins were found occluded by thrombi. In the posterior portion of the right optic thalamus was a recent extravasation of blood, extending anteriorly to the internal capsule. A smaller extravasation occupied a corresponding situation upon the opposite side. In addition, there existed cystitis and right-sided suppurative nephritis. Heart and uterus were normal.

Catheterization of the Biliary Ducts.—In a communication to the Société de Chirurgie, FONTAN (*Revue de Chirurgie*, 1891, No. 12, p. 1122) has reported a case in which the biliary passages were compressed by an abdominal neoplasm, with the development of cholemia. Relief was afforded by cholecystotomy, followed by repeated catheterization. In a second case, in a woman with cholelithiasis, the obstruction to the flow of bile was relieved by cholecystotomy, followed by catheterization and lithotripsy. From his studies upon the cadaver and the living, Fontan concludes that catheterization of the biliary passages is an indispensable adjuvant to cholecystotomy. The maneuver may be exploratory or therapeutic. It may be necessary to dilate a stricture. The procedure, difficult when the biliary passages are normal, is easily carried out when there has been retention of bile. The operation adds no dangers.

Aspergillus-mycosis of the Antrum of Highmore.—ZARNIKO (*Deutsche med. Wochenschr.*, No. 44, 1891, p. 1222) has reported the case of a woman, fifty years old, who complained of a sense of nasal obstruction and discomfort, of an offensive odor of the nasal secretions, of a feeling of occlusion of the left ear, and of frontal headache. On rhinoscopic examination, polypoid hypertrophy of both middle turbinated bones was detected. After removal of the excess of tissue it was found easy to introduce a sound into the antrum of Highmore of the left superior maxillary bone. Irrigation of the sinus brought away a moderate quantity of detritus, which, upon microscopic examination, was found to contain mycelia and spores of the aspergillus fumigatus. A continuance of the treatment afforded ultimate relief to the patient.

For Snake-bites.—As the result of a careful review of the subject, HOFFMANN (*Deutsche medizin. Zeitung*, No. 72, 1891) recommends the following mode of procedure in case of snake-bites. In recent cases, a deep crucial incision should be made and the wound washed with a five per cent. solution of carbolic acid or potassium permanganate. A white-hot iron should be applied to the floor of the wound. A ligature should be applied for from four to six hours between the bitten point and the heart. Stimulants (ether, camphor, ammonia, alcohol) should be administered to counteract the paralytic effects of the bite. Antiseptics: five per cent. solutions of carbolic acid, one-tenth per cent. solutions of mercuric chloride, are to be employed to prevent putrefaction and septic infection. The general condition must be supported.

Reaction from an Aqueous Extract Obtained from Bacteria—ROEMER (*Wiener klin. Wochenschr.*, No. 45, 1891, p. 835) has recorded a series of experiments made with an aqueous extract obtained from cultures of the pneumonia-bacillus and the bacillus pyocyaneus. Three guinea-pigs inoculated six weeks previously with the fluid obtained from tuberculous lymph-glands died shortly after having received injections of the extract. The injections were in each case followed by elevation of temperature. Post-mortem examination disclosed, in addition to the evidences of tuberculosis, enlargement of the lymphatic glands, serous effusions, and injection of and hemorahage in various viscera. Injections in three healthy animals were followed only by elevation of temperature.

Bilateral Tubal Pregnancy.—At a meeting of German naturalists and physicians BOILEAUX (*Münchener medicin. Wochensch.*, No. 45, 1891, p. 801), relates the case of a young woman in which he removed the left oviduct, containing a two months' fetus. The patient recovered and three months later presented a right-sided tubal pregnancy. A second operation was also successfully performed.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, JANUARY 23, 1892.

MEDICAL ASPECTS OF LIFE INSURANCE.

EVERY thoroughgoing Darwinian, SPENCER chief among all, is never weary of pointing out that modern civilization and sentimentalism works to the survival of the unfit, thus contradicting the plain trend of the ordinary laws of biological evolution. Devolution is in this way set against evolution, and instead of progressively strengthening and hardening the race, there are subtle forces sapping the vitality and rendering the more luxurious or civilized unfit for competition with the sturdier and biogenetically more obedient races. The great growth of civilized luxury is thus working to produce an ever-increasing army of social parasites, who, without aim or ability, live but to enjoy themselves, and make a miserable failure even of that. Indiscriminate charity, say the evolutionists, complicates the problem and exaggerates the natural supply of hangers-on, while the weak, the stunted, the diseased, the defectives of a thousand types, are nursed and coddled by protection and kindness to propagate their like, and thus handicap both the present and the future in the struggle for existence that is said to underlie all genuine elevation or even persistence of stock. Looked at from this standpoint exclusively, it has been contended that medicine itself is guilty of sustaining those in half-life, who, having received their death-sentence, postpone the execution, useless retainers, pensioners, and camp-followers of the much-enduring hard-pressed army of civilization. It has indeed been contended that had KOCH succeeded instead of failing to find an effective tuberculocide, he would thereby have done the world the greatest conceivable injury in licensing the weak-lunged, narrow-chested, deoxygenated failures to become the breeders of the coming race.

Now, however false and one-sided these views may be, and false and exaggerated we believe them, it is still always advisable to "heed the other opinion," know it, estimate it at its proper value, and meet it with logic and valor. We may shudder at the awful chasm such an unmoral and brutal lifting of the clouds discloses at our feet, but if the deep is there, the shudder itself renders us less steady of foot, and less possessed of aplomb. Happily, the confutation of this view is easy. If none other existed, the fact is patent that the workman's children are better breeders than those of the nabob. Parasitism begets in men debauchery and physiological degradation; in women, weakness, hysteria, and general good-for-nothingness. The children of the rich are "poor risks."

This, however, is but a too long preamble of a thought as to life insurance and the *rôle* that it is coming to play in our modern life. Is it, like luxury and vice, one of the great powers reversing the law of evolution and working to race-deterioration?

There can be no discussion as to the fact that hygiene, sanitation, increased comfort, and medical science have contributed to a lengthening of the average human life. But the life-insurance rates of premium continue so high that despite palatial offices, opera-bouffe salaries, and all that, it becomes a puzzle to presidents and boards what to do with the enormous surpluses constantly increasing.

Again, medical science has grown so shrewd that coming death may be long foreseen. Doubtful risks are refused, and thus the insured are those most certain of long life. Risk is thus reduced to a minimum and the surplus naturally grows.

The crux of the argument is reached when from the foregoing premises it is logically seen that with high premiums only the well-to-do and the long-to-live *can* insure. The poor—those on sentimental or religious grounds most needing insurance—*cannot*

afford insurance, and the unhealthy, or those of suspicious heredity or occupation—precisely those again that, from sympathetic or ethical reasons, should be most and best insured—cannot pass the examinations. Those children of the deceased parents who were rich enough and healthy enough to insure, are left with a competence that gives them a solid *locus standi* on the globe, and permits them again and always to multiply; whilst the poor workman and the "poor risk" who had neither the money nor the body to secure insurance for *their* children, early leave them sadly and doubly handicapped in the race of life.

Such undoubtedly *has been* the influence in the past. Need it, or will it be so in the future? Proofs are beginning to multiply that an entire change of front and of policy is, or is to be, undertaken. Some form of socialism is "in the air," fated to come. The life of the community is above that of the individual.

Already several counteracting forces are at work:

1. The shame and crime of dishonest "graveyard," infant, and "get-rich-quick" insurance (or *ass*urance) companies cannot blind the discerning to the fact that mutual and assessment companies, if properly watched and controlled, can give, and do give, trustworthy insurance at one-half or one-fourth the rates of the old companies. If, as need not happen, the company stops to-morrow, there is no exodus to Canada, and it has given value received up to date. There seems no reason why a precise amount of insurance should not be bought for a definite time, exactly as one buys so much coffee, house-rent, or a time-loan. And further, why should not the premium be dependent upon or in proportion to the medically-estimated probability of life for each case? At present it is either sheep or goats—two classes alone—but just as we all are a little wicked and a little good, so our chances of approaching death are of all degrees, and ratable in proportion.

2. Many companies are so transforming their business that it is becoming that of a savings-fund or investment company, the death-element an excluded, minor, or inconsiderable one.

3. Many companies that will not break the rule, wink at or whisper to their medical examiners to use not a little discretion. Albuminuria is becoming quite "physiological;" a little cardiac hypertrophy, a slight mitral murmur, a defective hereditary history, etc., are ignored. The printed rules stand, but the personal equation is given much play.

4. Companies are forming to insure those excluded by the rigid medical examiners of the billion-surplus companies, *i. e.*, accepting more doubtful risks, whilst yet other associations are forming to insure whoever will without any medical examination whatever.

5. Governmental insurance and systematic generalized pensioning is either under way or preparing to hoist anchor.

These and many more considerations that might be adduced, go to prove that "the bars are being let down." It is felt that, taken as a nation, our people are paying for their partial and unjustly classified insurance an excessive rate, and receiving therefor an insurance that discriminates unjustly between the classes and the masses. Individualism in insurance must have limits, and the common-health as well as the commonwealth, has its significance, duties, and demands. The tendency to socialistic legislation, the generalization, the extension of the pensioning system by corporations and by government, government insurance itself—all these and more, point to the fact that the health and death of every member of the community is of interest to every other member. Disease, if not self-interest, binds us all together and makes our own well-being depend upon that of every other. Preposterous as it may seem, the rates of premium are higher for the healthy and rich because the poor and unhealthy are excluded. A strange fact is coming to light: one of the richest of New York insurance companies, one that takes the most doubtful and dangerous risks, has one of the lowest death-rates. The life companies will soon learn that popularizing, broadening, and generalizing, making less stringent their medical examinations, will not only cheapen the premium, but strengthen the company and multiply its power for good.

Thus, sooner or later, one sees the medical aspect of a study, whatever it may be, comes uppermost. There seems no doubt of the ability of companies to lower the premium, or to lessen the rigidity of the medical examination, or to do both combined. As a skilled and directing chief officer of these great powers of modern society, the medical examiner for life insurance companies should use his encouraging influence toward extending to those less equipped with health or money, the beneficent action of the communal helping-hand in time of sickness and death.

PROGRESS IN PENOLOGY.

WE trust that every reader of THE NEWS will get and read the little volume, *Papers on Penology*, Second Series (and also the *Sixteenth Year-book*), issued by the New York State Reformatory at Elmira. We believe it may be had for the asking. It contains papers on the "Prisons of Great Britain," "Modern Prison Science," "The Philosophy of Crime and Punishment," "Criminal Anthropology," "New York's Prison Laws," "Prison Labor Systems," and "The Elmira Reformatory of To-day." It is to the last-named article that we especially direct attention. With just and noble pride the editor shows the advances made since the establishment of the institution in 1876, and how to-day it is a great compulsory educational establishment for improvable felons, in which, at the present time, some 1500 persons are undergoing a systematic process of redintegration and preparation for again becoming ordinary citizens. The indeterminate sentence is a basic principle. Likening, *not* identifying, crime and disease, it is held that the criminal should be kept under educational control until convalescent—that is, until morally, intellectually, and physically capable of earning a livelihood, and of maintaining a disposition consonant with the customs and necessities of society. The Reformatory prescription homologizes with the famous three R's, except that here it is the three M's that are required—Mental, Moral and Manual training. In 1890 the percentage of probable reformations was placed at 82.2, or 2147 of the 2611 paroled since 1876. The paroled are sent to the care of an agent of the Reformatory in the city or town in which they have secured employment, and he unobtrusively observes their behavior and mode of life for six months, and indorses their monthly reports to the general superintendent of the institution. If their conduct has been examplary during this time their absolute release from State service is authorized. The trade learned in the Reformatory assures them employment when on parole or discharged. In 32 distinct trades 953 men are now receiving instruction. Nearly 70 per cent. of those admitted were wholly illiterate.

Physicians will be most interested in the report concerning the systematic physical culture of dullards and weaklings—youths not idiotic, but too dull to take up work in the technological departments or to keep pace with the classes in school-study. To reclaim this class has been one of the severest tasks of the managers. The remarkable success following physical drill and exercise, massage, etc , led to an extension of the system to others, and to the establishment of a gymnasium. From March, 1890, to October 1, 1891, there were 212 under the peculiar gymnastic treatment. Of this number only 13 did not chew or smoke tobacco, and only 25 had not been addicted to alcoholic drink. One-fourth acknowledged themselves victims of venereal disease. The causes most frequently assigned for their selection for the physical culture classes were general debility, anemia, myalgia, physical degeneration, masturbation, scrofula, etc.

The outrageous Prison Bill of 1888 interdicted all machine labor for revenue, and how this apparent curse was turned into a blessing by the inauguration of military drill forms a pleasing episode, and, as in the case of the physical culture classes, an instructive example of the power of physical training to educe mental and moral results of the utmost good.

CONSANGUINEOUS MARRIAGES.

THERE is popularly a very widespread, and in its results, beneficial prejudice against the marriage of "blood relations;" but late researches tend to prove that this prejudice, though practically of good effect, is not based upon scientifically correct observation and reasons. Consanguineous marriages do not, as commonly supposed, tend to produce insanity and idiocy in the children, but according to the simple law of cause and effect they tend to intensify the qualities, healthy or diseased, good or bad, of the parents. If the two parent stocks have an inherited tendency to insanity, the offspring will have that tendency doubled. If the consanguineous parents are both tuberculous the children will have precisely the same, but no greater, probability of being tuberculous than if the parents had not been related. But if the consanguineous parents are without pathological taint, and both possess exceptionally desirable or peculiar characteristics, the offspring will inherit the exceptionally pure and strong type intensified and perfected. Stock-raisers take advantage of this law, and by in-and-in breeding they quickly bring a herd to surprising perfection in a short space of time.

But the danger of in-and-in breeding in human beings is that the pure, healthy stocks are hard to

find. We are less "normal" than our animals. Almost every family has some pathologic skeleton in the closet that cross-breeding keeps just below the threshold of observation, but which doubled with another and (in the same family) generally identical or similar abnormalism, at once appears exaggerated in the child, to work decay and ruin. The Persian and Egyptian kings habitually married their own sisters, and even their own daughters, without disadvantage to their offspring. Such instances and the success of cattle-raisers show us that the condemnation of marriage between relatives rests upon the fact of the impurity and generally pathologic condition of civilized man, and not upon any essential biologic law. In itself the blood-relationship is innocent, and under different conditions might even be utilized to elevate the quality of offspring and of the race. It is a sort of negative safety we secure by "cross-fertilization," that shows how near the danger-line humanity is running in its civilized race-degeneration.

Another, and a somewhat unexpected result of the scientific study of this subject has lately been made clear by the studies of two French investigators. They chose a commune of fisher-folk in which, from interesting conditions, there had been highly exceptional social segregation, and in which for two hundred years there had been constant intermarriage of cousins and the descendants of cousins. Of two hundred and sixty marriages occurring in five years, sixty-three were consanguineous. A study of the results of these marriages confirms the previous negative conclusions of other observers as to insanity, idiocy, physical defects, etc. But the new fact clearly established is the decided tendency of these marriages to prove sterile, though this defect did not seem to be transmitted to the children of the consanguineous parents.

It should be noted, however, that the people among whom these studies were made were seafaring, hardy folk, living under circumstances of simplicity and healthfulness, contrasting very sharply with the influences and habits of urban or more "civilized" people.

OBITUARY.

Henry I. Bowditch.—Surrounded by everything that should accompany old age, another veteran has passed from our ranks, and it becomes our duty to pay a tribute to his memory. Dr. Bowditch belonged to a remarkable group of American students that, between the years 1830 and 1840, returned from Paris laden with the new knowledge of physical diagnosis and enthusiastic followers of the numerical method as expounded by their master, Louis. Among them were Gerhard, of Philadelphia, *facile princeps* of American investigators in diseases of the chest; James Jackson, Jr., a young Lycidas, who died ere his prime; Power, of Baltimore, cut off in the fulness of his work; and there remain with us, happily, Oliver Wendell Holmes, the elder Shattuck, and Alfred Stillé. Truly a notable group of men! Dr. Bowditch's early work consisted in the introduction, through translations, of Louis's important works to the profession, and in the popularizing by a little work the methods of stethoscopy. He very early became interested in chest-diseases, and was associated with Dr. Morrill Wyman in the introduction of aspiration. To appreciate his position on this question in the year 1852 let anyone turn to *The American Journal of the Medical Sciences* of that date, and he will find our present ideas there expressed, many years before Dieulafoy's invention, and even prior to Trousseau's strong advocacy of paracentesis in pleural effusion. Unquestionably this is the work by which he is perhaps best, and will be longest known. All of his contributions to the subject of pleurisy, including his latest study of its relation to tuberculosis, bear the mark of the thoughtful, progressive mind. The question of the connection between soil and phthisis engaged his attention for many years, and he was a pioneer in advancing sound views with reference to the climatic and fresh-air treatment of tuberculosis. Sanitary problems occupied many of the later years of his life, and he rendered most efficient service as member of the National Board of Health. Personally, Dr. Bowditch had the charm of manner that so often accompanies an impulsive, generous nature. Even his faults were lovable, but his most characteristic trait was a boyish enthusiasm perfectly delightful to see as he advanced in years. There was, however, a sterner side to his nature, and the wrongs of the Nation and of the race found in him an implacable enemy. The New England spirit never dwelt in a more congenial frame, and in the great struggle of the Nation he was an enthusiastic abolitionist and a devoted supporter of the Union. Rarely has the profession of this country had a more representative member—high-minded, generous, and outspoken—than Henry I. Bowditch, whose name will long be cherished by those who regard such lives as the very leaven of the life we live.

SELECTIONS.

WANTED—A CURE.

The influenza is once more in the air, wafted hither and thither throughout the habitable globe, a formidable, disabling, and fatal pandemic. Once more we are urgently asked on all sides, "Have we a specific? Can we offer a cure?" It is the old delusion and the everlasting and unreasoning, but excusable, impatience for the miraculous and the impossible. "Disease comes by Providence and goes by medicine;" that is a durable and popular formula. Of specifics for sale there are, of

course, a legion. To sell them is the business of the quacks; the Matteis, the Holloways, the Morrisons abound in specifics. There are a dozen available for cholera, for typhoid, for smallpox, for hydrophobia, for carcinoma—all equally plausible and equally useless except for commerce—and why not for influenza? But is there a specific for any disease? It is more than doubtful. The more we know of the nature and cause of disease, of its origin and life-history, the less we are inclined even to expect the discovery of specifics. Disease we know not as an entity, an enemy to be struck down with a club, or to be expelled by a drug, but as a process, the change of tissues and of fluids, the growth of a microbe, the proliferation of a cell, the secretion of a virus. We can modify the processes, we can lessen their virulent products, we can fortify against their worst effects; we can aid the evolution and perhaps guide it to health; sometimes we can arrest it; and often we can anticipate it. Thus we know how to ward off many diseases. Cholera, typhoid, smallpox, hydrophobia are enemies whom we can meet at the gate and forbid their approach. Deaths from either of these preventable diseases are, for the most part, violent deaths, inflicted by the ignorance of the people, the neglect of the sanitary authorities. *Populus vult mori.* In their search for specifics they parley with the enemy and lose their lives. Of influenza we know less than of most other infections; it is aërial, communicable from person to person, and along the lines of travel. For it, as for scarlet fever, we have only isolation as a preventive and palliatives as a treatment. Perhaps one day we shall know more; but there does not seem any likelihood of the discovery of a specific, and judging from numerous analogies it is far from certain that there is in this any ground for reproach. At any rate it comes badly from a public and from a generation which is content to leave Great Britain without even one Institute of Preventive Medicine, and which is left to an appeal for funds from a Lister and a Roscoe to found such an institute—in which lies a chief hope for further life-saving and the advance of preventive and curative knowledge—while millions are lavished on weapons of destruction, or the more obvious means of charitable relief to physical suffering; and finally on the purchase of fraudulent "specifics."—*British Medical Journal*, January 2, 1892.

THE MEDICAL GUILD.

"WHAT, then, are the remedies for these evils which stare the doctor in the face at the very threshold of his career, and embitter his life at a time when it should be radiant with promise?

"1. The limitation of the number of new doctors by the only legitimate measure—the rigid examination of all applicants for practice. Men may be allowed to obtain diplomas in this free country *ad libitum*. Colleges may multiply and send out their hordes of full-fledged doctors. But the medical profession must, for its own interests, but more even for the interest of the gullible public, continue to labor for State examinations. These will, if properly conducted upon some general plan, weed out not only incompetent practitioners, whose numbers, alas! are only too large, but they will also weed out incompetent colleges by holding the latter up to just reprobation in the exhibits of the rating of their students.

"2. The course of instruction in our colleges should be, and as a corollary of the first would be, made more thorough. The exaction of a preliminary education, too, would aid in lengthening the time necessary for the entrance into practice. Thus the over-supply of doctors would be decidedly inhibited, and this would inure not only to the good of the profession but also to the general good.

"A better *entente* should exist among the members of the profession. We should imitate the trades-unions, who pass general laws for the protection of their members, and who adhere to them to the bitter end. Worthy, struggling practitioners should be helped, just as the worthy mechanic is helped, out of a common fund, if his necessities arise, as they often do, from his strict adherence to the rules of the medical guild."—From an editorial in the *Dietetic and Hygienic Gazette*, Jan., 1892.

RAILWAY ACCIDENTS.

FROM the advance copy of the *Third Annual Report on the Statistics of Railways* for the year ending June, 1890, we glean the following interesting facts:

The total number of persons reported by railways as killed during the year was 6,334, and the total number reported as injured was 29,025. Of the total number killed 2451 were employés, 286 passengers, and 3597 were classed as "other persons." In this latter figure are included the large number of suicides. Of the total number injured 22,394 were employés, 2425 passengers, besides 4206 unclassified. If the number of employés killed be assigned to the total number, it appears that one death occurs for every 306 men employed on the railways, and one injury occurs for every 33 men employed. The largest number of casualties occur to men engaged directly in handling trains. Thus, while trainmen represent but 20 per cent. of the total number of employés, the casualties sustained by them account for 58 per cent. of total casualties. A passenger riding continuously at the rate of 30 miles an hour might expect immunity from death by railway accident for 158 years; but an engineer, a brakeman, or a conductor, under the same conditions, is liable to a fatal accident at the expiration of 35 years. The most common accident to which railway employés are liable results from coupling and uncoupling cars. The total number of casualties that can be traced to this source are 7842, of which 369 were fatal. Of this number trainmen sustained 6073 accidents, of which 265 were fatal. The most fatal accidents, however, result from falling from trains or engines, the total number of deaths assignable to this cause being 561, of a total of 2924 casualties. Of this number trainmen sustained 456 deaths and 1838 injuries. Railway travel is found to be the least safe in the States south of the Potomac and Ohio rivers, Groups IV and V. Thus, in this territory, 1 employé is killed for each 241 men employed, and 1 trainman is killed for each 65 men employed. One passenger is killed for each 838,555 passengers carried. In the States lying east of Illinois and north of the Ohio and Potomac rivers, that is, Groups I, II, and III, 1 employé is killed for each 290 men employed, and 1 trainman for each 107 men employed;

1 passenger is killed for each 2,519,851 passengers carried. The statistics of the Western territory show that railway employment and travel is slightly safer than in the Southern States.

THE CARDINAL TRUTH OF CLIMATE-THERAPY.

"THE one great truth stands ever before the eye of the modern surgeon—cleanliness; absolute, scrupulous cleanliness leads to success. Change of climate for consumptives is extremely valuable, but it involves many disadvantages which are far more fatal to its success than the abuse of antiseptics is in wound-treatment, and yet we continue to send patients away from comfortable homes to uncomfortable hotels and boarding-houses, or incomplete sanitaria, where many disadvantages in diet and probable indiscretions in exercise neutralize the most valuable element of all appropriate climates—pure air. It will be a glorious day for medicine when the physician will recognize that the *constant exposure of the phthisical patient to pure air* is the cardinal truth of climate-therapy, as cleanliness is now recognized by the surgeon in wound-treatment."—DR. SIMON BARUCH in the *Dietetic and Hygienic Gazette*, January, 1892.

CORRESPONDENCE.

CHICAGO.

U. S. Medical Secretary of Public Health—Hospital for Contagious Diseases—The Charity Ball—Medical Staff of Cook County Hospital—Springfield Capital District Medical Society—Preparations for an Exhibit of the Status of Sanitation in 1893.

REGARDING the work of the committee appointed at the last meeting of the American Medical Association to memorialize Congress to create a cabinet officer to be known as the Medical Secretary of Public Health, the daily press of this city is highly in favor of the establishment of such a department at Washington. It has shown that international sanitation will be an easy outgrowth of the perfection of sanitary precautions at home. The United States has a natural right to be considered a leader in all matters pertaining to the public health. As the recipient, also, of a perennial stream of immigration from foreign countries, this nation is entitled to considerable latitude in impressing on other governments its views on sanitary matters. The creation of a department of public health would have the dual advantages of increased protection at home and the diffusion of sanitary education abroad.

The new County Board has taken its first actual step toward the erection of a hospital for contagious diseases. A resolution was introduced at a recent meeting directing the county architect to prepare plans for a structure suitable for this purpose, to be built on the grounds of the County Hospital at a cost not exceeding $50,000. The resolution was adopted. It cannot be said that the Board has acted with undue precipitancy. Considering the state of public feeling, as it has been expressed in the press and at large, enthusiastic, and even vociferous mass meetings of the people, it may even seem to not a few persons that the Board has been more deliberate than the circumstances required. These persons believe that, whatever else be done or left undone, a hospital for contagious diseases must be provided forthwith, if only to avert a distressing and calamitous scandal.

From $21,000 to $25,000 were cleared by the recent Charity Ball, as against less than $20,000 netted by that of last year. St. Luke's Hospital is to have one-third. St. Luke's, founded twenty-six years ago, is, as it ought to be, one of Chicago's pet charities. Another third will go to the Women's and Children's Hospital, also founded in 1865, and the rest of the money will be divided equally between the Visiting Nurses' Association, the charity work of the World's Fair, and the Margaret Etter Crèche, which takes care of small children while their mothers are out at work.

The Public Service Committee recently selected the medical staff of the Cook County Hospital. By a former resolution the staff was made to consist of thirty-six physicians, divided among the schools as follows: Regulars, twenty-three, homeopathic six, and eclectic five. All were selected with the exception of the members to represent the homeopathic school. In regard to this a letter was received from the Homeopathic Society, requesting that eight physicians named in the letter be elected to represent that school. As six only are allowed, the society was informed that they would be allowed to name them. Several of the old staff secured reëlection. The majority, however, are new men. The committee started out by allowing each commissioner to name a man. The fifteen regular physicians chosen in this way were: Drs. J. B. Herrick, A. Babcock, J. Boas, P. J. Rowan, J. Price, J. J. Bouffler, D. D. Owsley, C. W. Johnson, G. L. Morganthau, E. W. Lee, J. Frank, J. O. Hobbs, C. W. Earle, J. B. Murphy, and Denslow Lewis. Physicians were then placed in nomination, and eight of them selected by ballot. They were: Drs. J. H. Curtis, Christian Fenger, N. Senn, J. R. McCullough, Bayard Holmes, Arthur Blavin, C. Sandberg, and A. J. Ochsner.

The Capital District Medical Society was organized recently at Springfield. It includes the regular physicians of Springfield, Decatur, and Jacksonville, and the adjacent territory. The following officers were elected: *President*, Dr. T. A. Wakely, Jacksonville. *Vice-Presidents*, Drs. Geo. N. Kreider, Springfield; W. B. Hostetter, Decatur; and L. H. Clampett, Jacksonville. *Secretary*, Dr. B. B. Griffith, Springfield. *Treasurer*, F. J. Brown, Decatur. *Judicial Council*, Drs. C. E. Black, E. A. Prince, L. P. Walbridge, T. J. Pitner, and E. A. Walbridge. About fifty physicians were in attendance.

In pursuance of a call by Dr. Benjamin Lee, Secretary to the Pennsylvania State Board of Health, a number of prominent sanitarians, health officials, and others connected with sanitary matters, met in conference with the Hon. Selim H. Peabody, Director of the Section of Liberal Arts, and Dr. John H. Rauch, Chairman of the Committee of the American Public Health Association, on a World's Fair sanitary exhibit. The delegates met at 10 A.M., January 14th, in the directors' room. There were present: Dr. Benjamin Lee, Secretary to the Pennsylvania State Board of Health; Dr. Henry B. Baker, Secretary to the Michigan State Board of Health; Dr. Charles N. Hewitt, Secretary to the Minnesota State

Board of Health; Dr. C. D. Smith, member of the Maine State Board of Health; Dr. C. N. Metcalf, Secretary to the Indiana State Board of Health; Dr. F. W. Reilly, Secretary to the Illinois State Board of Health; Dr. J. T. Reeve, Secretary to the Wisconsin State Board of Health; Dr. S. P. Wise, member of the Ohio State Board of Health; Dr. H. H. Clark, member of the Iowa State Board of Health; Dr. M. O'Brien, Secretary to the Kansas State Board of Health; Dr. Charles McLellan, member of the Provincial Board of Ontario; Dr. John D. Ware, Health Commissioner of Chicago: Dr. J. H. D. McShane, Health Commissioner of Baltimore; Dr. U. O. B. Wingate, Health Commissioner of Milwaukee; Dr. D. S. Shellaberger, Health Commissioner of Sioux City; and Dr. John H. Rauch, of the American Public Health Association.

Dr. Rauch, in calling the conference to order, stated the purposes of the conference, and, after a general discussion by the delegates and a statement of the plans and resources of the "liberal arts" department by Prof. Peabody, it was resolved that the members of the conference coöperate with the committee of the American Public Health Association and with the general plan and scope of the World's Fair auxiliary congresses under the Hon. C. C. Bonney.

The Chairman, Dr. Rauch, was authorized to appoint a committee of seven to formulate plans for the State sanitary exhibits, and at the evening session of the conference the members of this committee were instructed to submit their suggestions and views to the Chairman, Dr. Benjamin Lee. The remaining members of the committee appointed by Dr. Rauch, are: Dr. Henry B. Baker, of Michigan; Dr. C. N. Hewitt, of Minnesota; Dr. J. T. Reeve, of Wisconsin; Dr. J. D. Kennedy, of Iowa; Dr. C. N. Metcalf, of Iowa; and Dr. F. W. Reilly, of Illinois.

THE CAUSE OF THE INUTILITY OF ERGOT IN THE INTESTINAL HEMORRHAGE OF ENTERIC FEVER.

To the Editor of THE MEDICAL NEWS,

SIR: As an addendum to the communication in THE MEDICAL NEWS of January 9th, relating to the therapeusis of intestinal hemorrhage in enteric fever, I would like to state that the inutility of ergot in this condition has a source deeper and a significance wider than was noted by your correspondent. A hemorrhage of sufficient gravity in enteric fever to demand a resort to specific measures to cause its cessation usually emanates from an eroded vessel. Ergot here, as in the hematemesis of gastric ulcer—also commonly dependent upon the erosion of an artery—is not only useless, but absolutely harmful, since, from its constricting effects on the vessels being limited to the arterioles, and causing resistance *à fronte*, when a vessel larger than an arteriole is the source of hemorrhage, the increased pressure results in augmentation of the bleeding. This fact, though of vast importance, is apparently known to few. It was pointed out some time ago by Dr. A. H. Smith, in a communication to THE MEDICAL NEWS relating to the hematemesis of gastric ulcer. The principle underlying it should govern the administration of ergot for the control of hemorrhage—to use in that produced by capillary oozing, to avoid in that resulting from rupture of a vessel larger than an arteriole.

Still another important objection to the employment of ergot in the intestinal hemorrhage of enteric fever is the fact that active peristaltic movements are thereby produced, the effects of which would inevitably be to disturb the ulcerated bowel, to provoke more rapid separation of the sloughs, and to aggravate the tendency to bleeding.

These dangers are not imaginary, and are more imminent than that of gangrene observed by Dr. Rodman in his cases.

Very respectfully yours,

D. D. STEWART, M.D.

PHILADELPHIA.

REVIEWS.

PTOMAÏNES, LEUCOMAÏNES, AND BACTERIAL PROTEIDS. By VICTOR C. VAUGHAN, M.D., and FREDERICK G. NOVY, M.D. Second Edition. Philadelphia: Lea Bros. & Co., 1891.

THE second edition of this work will doubtless have the same favorable reception as was accorded the first three years ago. No more clear, concise, and readable exposition of the obscure subjects with which the work has to deal has been written. The work is properly a standard.

This second edition gives evidences of the remarkable progress in the branch of science of which it treats on its very title-page, in the addition of the term "bacterial proteids," designating a group of substances not previously included in the work, and indeed until recently unknown. Throughout the book are further proofs of the advances in knowledge, as in the articles on tuberculosis, diphtheria, swine-plague, rabbit septicemia, pneumonia, and malignant edema, which are entirely new, and in that on tetanus, which has been greatly extended. The chapters on "The Nature of Immunity-giving Substances," "Bacterial Products which Favor the Development of Infectious Diseases," and on "The Germicidal Proteids of the Blood," are new, and contain matter of the greatest interest and importance.

We agree with the authors as to the propriety of rejecting the term "toxalbumins," and adopting the more correct one, "bacterial proteids." However, even with this change, the nomenclature cannot be regarded as satisfactory; we should have been glad to have had the opinion of the authors as to the nomenclature proposed in THE MEDICAL NEWS of July 18, 1891.

ESSENTIALS OF NERVOUS DISEASES AND INSANITY: THEIR SYMPTOMS AND TREATMENT. A MANUAL FOR STUDENTS AND PRACTITIONERS. By JOHN C. SHAW, M.D., Clinical Professor of Diseases of the Mind and Nervous System, Long Island College Hospital Medical School, etc. Forty-eight original illustrations, mostly selected from the Author's private practice. Philadelphia: W. B. Saunders, 1891.

THIS little volume, which is No. 21 of "Saunders's Question Compends," contains 190 pages. In his preface the author states that the book is intended to be used "somewhat as a primer for advanced students."

There is much truth in the saying that it is more diffi-

cult to write a small treatise than a large volume. The author of a small book must know what to omit as non-essential; he should say what he has to say in clear and concise language; he must emphasize essential points; he should eschew discussion of controversial matters and rare diseases. We do not think Dr. Shaw has succeeded very well in surmounting these difficulties. His classification of disease seems to us unfortunate and misleading. For instance, peripheral neuritis, alcoholic neuritis, and multiple neuritis, are classed under the head of "Injuries of Nerves." Imperative conceptions, which are symptoms (just as delusions or hallucinations are), are treated as a separate disease under the head of "Degenerative Insanities." Syringomyelia and acromegaly, of interest to the specialist chiefly as rare and curious diseases, are not of enough importance to the student to justify five pages of description. On the other hand, the insufficient space of four pages is devoted to epilepsy and chorea. In dealing with the treatment of melancholia the author omits to call attention to precautionary measures against suicide. The description of paranoia is quite a good one—perhaps the best in the compend. But, taken as a whole, we cannot commend the book.

NEWS ITEMS.

The International Executive Committee of the Pan-American Medical Congress.—The Committee on Organization of the Pan-American Medical Congress, at its meeting at St. Louis last October, elected the following International Executive Committee: The Argentine Republic, Dr. Pedro Lagleyze, of Buenos Ayres; Bolivia, Dr. Emelio Di Tomassi, of La Paz; Brazil, Dr. Carlos Costa, of Rio de Janeiro; British North America, Dr. James F. W. Ross, of Toronto; British West Indies, Dr. James A. DeWolf, of Port of Spain; Chile, Dr. Moises Amaral, of Santiago; United States of Colombia, Dr. P. M. Ibanez, of Bogotá; Costa Rica, Dr. Daniel Nuñez, of San José; Ecuador, Dr. Ricardo Cucalon, of Guayaquil; Guatemala, Dr. Jose Monteris, of Guatemala Nueva; Hayti, Dr. D. Lamothe, of Port au Prince; Spanish Honduras, Dr. George Bernhardt, of Tegucigalpa; Mexico, Dr. Tomés Noriega, City of Mexico; Nicaragua, Dr. J. I. Urtecho, of Grenada; Peru, Dr. J. Caramina Ulloa, of Lima; Salvador, Dr. David J. Guzman, of San Salvador; Spanish West Indies, Dr. Juan Santos Fernandez, of Habana; United States, Dr. A. Vander Veer, of Albany, N. Y.; Uruguay, Dr. Jacinto DeLeon, of Montevideo; Venezuela, Dr. Elias Rodriguez, of Caraccas; Hawaii, Paraguay, Santo Domingo, the Danish, Dutch, and French West Indies are not yet organized. Nominations of local officers have been received from a majority of all of the members of the International Executive Committee, and a number of the lists have been confirmed by the Committee on Organization.

Laboratory of Hygiene, University of Pennsylvania.—It is announced that the laboratory of hygiene of the University of Pennsylvania will be opened for practical work on February 1, 1892. The building contains chemic and bacteriologic laboratories, special rooms for investigations upon air, water, food, soil, clothing, etc., workshops and photo-micrographic rooms, and special arrangements for demonstrating the principles and practice of heating and ventilation, house-drainage, etc. The work of the laboratory will be under the charge of the director, Dr. John S. Billings. Dr. A. C. Abbott has been appointed first assistant, and Dr. Albert A. Ghriskey, assistant in bacteriology. A course in practical hygiene and an elementary course in bacteriology, each of eight weeks, have been established.

University of Michigan.—The first ward of the new hospital of the medical department of the University of Michigan was formally opened January 20th by the Governor of the State. An address on "The Hospital: an Element and Exponent of Medical Education," was delivered by Dr. Albert L. Gihon, Medical Director, United States Navy.

The hospital is provided with modern appliances. The ward just completed contains a clinical amphitheater, consultation-rooms, offices, and accommodations for eighty patients. It has cost about eighty thousand dollars. The plan provides for three additional wards, the erection of one of which will be begun during the current year.

Alvarenga Prize of the College of Physicians of Philadelphia.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, amounting to about one hundred and eighty dollars, the income for one year of the bequest of the late Senor Alvarenga, will be made on July 14, 1892. Essays intended for competition may be upon any subject in medicine, and must be received by the secretary of the College on or before May 1, 1892. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college.

The Medical Faculty of the University of Tübingen has offered two prizes for the best essays on each of the following subjects: "A Critical Résumé of Recent Theories of Glaucoma, Preferably Based upon Original Experiments upon the Eyes of Animals;" "The Influences, if any, Exerted by Antipyrin, Antifebrin, and Phenacetin upon the Conditions that Follow the Excessive Use of Alcohol."

The Therapeutic Gazette has undergone an editorial change. Dr. Robert Meade Smith has retired. Dr. Hobart Amory Hare has become editor-in-chief; Dr. George E. de Schweinitz, editor of ophthalmic and aural therapeutics; and Dr. Edward Martin, editor of surgical and genito-urinary therapeutics.

Books and Pamphlets Received.

Intubation of the Larynx. By Carl H. von Klein, A.M., M.D. Reprint, 1891.

Saunders's Pocket Medical Formulary, with an Appendix Containing Posological Table, Formulary and Doses for Hypodermatic Medication, etc. By William M. Powell, M.D. Philadelphia: W. B. Saunders, 1891.

The Supreme Passions of Man. No. 1. By Paul Paquin. Battle Creek, Mich.: The Little Blue Book Company, 1891.

Is a Child Viable at Six and a Half Months? By Llewellyn Eliot, M.D., of Washington, D. C. Reprint, 1891.

A Case of Congenital Cystic Elephantiasis. By W. Reynolds Wilson, M.D. Reprint, 1891.

ORIGINAL ARTICLES.

OLEOMARGARIN.[1]

BY G. C. CALDWELL, B.S., PH.D.,

PROFESSOR OF AGRICULTURAL AND ANALYTICAL CHEMISTRY, CORNELL UNIVERSITY, ITHACA, NEW YORK.

NEARLY all of the ordinary natural fats and fatty oils consist essentially of three glycerides—palmitin, stearin, and olein. The difference in odor and taste whereby they are distinguishable from one another is due to *very small* quantities of other substances that they contain, and that are always associated with them in their natural or in their prepared condition. Castor oil, olive oil, tallow, and lard oil are unmistakably different to our senses of taste and smell; but all of them alike consist essentially of palmitin, stearin, and olein, this mixture being scented and flavored by small quantities of the foreign substances mentioned.

There is an important difference between the fat in milk and some other fats, on the one hand, and the fat of tallow, lard, palm-nut oil, etc., on the other hand—a distinction all the more interesting because it exists between the fat that is deposited on the carcass and that which is secreted in the milk of the same animal. Butter and tallow are mostly but mixtures of olein, palmitin, and stearin, the same three glycerides that are so widely distributed in the fats everywhere; but butter-fat contains, besides the four other glycerides, butyrin, caproin, caprylin, and caprin; but as even these glycerides are as tasteless and odorless as any of the others when purified, nothing of the odor or flavor of butter can be credited to them. This being the case, then, it is only natural that the attempt should be made to give a butter flavor and aroma to the more abundant and much cheaper fats of the animal carcass. It is only a question of transforming the carcass-fat into a fat of the same consistency as that of butter at ordinary temperature, removing its characteristic flavor, and substituting therefor the butter flavor. The first change is easy enough, consisting as it does simply in taking out a certain proportion of the less fusible stearin and palmitin, so as to leave a residue with a larger proportion of olein, and therefore softer at common temperatures, as butter is softer than tallow; since odor and flavor are largely due to volatile and soluble substances, steaming and washing the fat will leave a sufficiently odorless and tasteless product as a basis for receiving the desired butter flavor. It is plain that the available quantity of this product from the carcass-fat is much larger than the available quantity of the material like which it is to be flavored—the butter-fat of milk. How, then, shall this flavor be imparted?

We know quite well that when it comes to communicating the flavor of lemon, strawberry, or raspberry to ice-cream or cake, not even the shadow of the fruit need be cast over the material to be thus flavored; much less need any of its substance be incorporated with the cream or dough. The chemist in his laboratory can manufacture at least many of these flavoring essences more cheaply than they can be made from the fruits. But I am not aware that any essence of cow's butter has ever yet been prepared. A clean mixture of olein, stearin, and palmitin, no matter how carefully the proportions of these three ingredients might be adjusted to secure the right consistency, and no matter how deftly colored, would never pass for butter even with the least fastidious. Therefore the amount of artificial salable butter that can be made from this oleomargarin is limited by the degree of thinness with which real butter-fat, with its butter flavor, can be distributed through it and produce a resemblance to butter.

Although margarin does not occur in animal fats, its name still remains associated with the less fusible part of animal and vegetable fats, although this mixture is one of palmitin and stearin only; and since olein from the other series of glycerides is always associated with palmitin and stearin in these fats, we have the familiar name oleomargarin for this manufactured product; the same name could just as appropriately be given to any fat, and just as incorrectly also, but it has come to be a trade name the meaning of which is understood by everybody. Only when this oleomargarin, or oleo oil, as it is sometimes also called, is churned with milk and water, do we have the real artificial butter or butterine.

The fat, said to be only the caul fat, and possibly so in all the large manufactories, is washed in cold water, surrounded with ice until the animal heat is removed, cut up fine, heated to from 120° to 150° F., allowed to stand until the fat is separated clear from the tissue, then kept in wooden tanks for from twenty-four to thirty-six hours, in a warm room at

[1] Abstract of a lecture delivered before the Franklin Institute, Philadelphia, January 18, 1892.

such a temperature as will favor the crystallizing out of the largest part of the stearin with a little of the palmitin; then, in hydraulic presses in the same room, the solid fat is separated from the liquid, or the oleo oil, as it is called. Another product is prepared from lard in a similar manner, except that no stearin is removed from it, and this goes by the technical name of "neutral." From this "oleo oil" and "neutral," the oleomargarin and butterine are made, more "oleo" being put in if the product is to go to a cold climate, more "neutral" if to a warm one, the proper mixture of the two being churned in a steam-jacketed vessel, with about 48 gallons of milk to 2000 pounds of the fat, or 80 pounds to 500; it is stated that cream is sometimes used in the place of milk; butter-color, or annatto, is used unless forbidden. The churned product is suddenly cooled by allowing it to run out on to ice or cold water, then washed, salted, and worked as butter usually is. The use of lard is comparatively recent, and it is interesting to notice that the first manufacturers were very indignant when it was attempted in the West to palm off a product from lard as oleomargarin; they used about the same contemptuous expressions as the dairymen used so freely when speaking about the oleomargarin.

Such is the substance of the process for the manufacture of artificial butter in its various forms. As to the quality of the product, in the first place it keeps well, if made from clean materials. A second important quality is such close resemblance to genuine butter of a fair quality, that often only experts can distinguish the one from the other. But by far the most important question concerning oleomargarin as food is that of its wholesomeness, as compared with butter. The answer to this question turns on two points: first, the quality of the materials used in its manufacture, and second, its digestibility when properly made. It may be safely said that no other food-product has been so much discussed in respect to its healthfulness, large pecuniary interests being involved.

In the first place, what bearing has the quality of the materials used in the manufacture of oleomargarin on its wholesomeness? Concerning this, most damaging statements have been made, especially at the very beginning of the oleomargarin war. If even the half of these statements were true, then certainly a committee of the New York Legislature, intent on making in its report the very worst showing possible against oleomargarin, in support of a very stringent prohibitory law, would have obtained similar ones from some of the numerous witnesses cited before it; but a careful examination of the whole printed report of 275 pages reveals no worse statement than this: that not merely the caul fat, or that on the membrane investing the viscera is used, but also that on the intestines themselves; and this witness affirms that this fat was in the vats mixed up with some of the excrementitious matters naturally associated with fat in that state. But in another place in the same report the manager of the same factory testifies that not all of the fat received at the establishment is used for oleo, since they manufacture tallow also, and that but a very little of the intestines remains attached to that part of the fat used for oleo. The first witness did not testify that he actually saw the foul fat that he described worked into the oleo oil. No sound proof is anywhere given that such extravagant statements as those that I have quoted are founded on fact, or were anything more than conjectures and guesses.

But oleomargarin has been no less bitterly and extravagantly attacked on another line, namely, with reference to what has been found in it, especially on microscopic examination. Prof. Michels, of New York, in 1878, stated that he had found cells of a suspicious character and fragments of muscle and tissue in some of the samples that he examined; these, however, he acknowledged came from the chopped stomach then used according to the original Megé patent; but he affirmed that trichinæ might get into the butter in this way, and that the heat to which the fat was subjected in the course of the rendering and the crystallizing would not be high enough to kill them. In 1880 a Prof. Piper gave in a Chicago newspaper some startling drawings of what he had seen in samples of oleomargarin butter under the microscope—shreds of animal tissue, spores, and a form often found by him in foul water; and in another paper he gave, side by side, figures of actual tapeworm eggs, and of forms very much like them in appearance, from oleomargarin. Passing on to a later date, when the addition of chopped stomachs and mammary glands had been entirely given up, very little is reported of observations of this kind. A Prof. Nachtrieb is quoted as finding in a sample of butterine parasites that are present in the rectum of swine and in the evacuations of patients suffering from diarrhea; but without further knowledge as to the reliability as a microscopist of this professor, one should give little weight to such a startling statement.

Two samples of artificial butter were reported by an official of the Department of Agriculture, out of ten, as being full of fungi and their spores; but as all of them were reported as being in a bad condition even for samples of butterine, such an observation furnishes no reliable evidence as to the usual quality of the substance; further, the reputation of this observer was not of the best.

The answer to the question of the wholesomeness

of the oleomargarin must then be sought on other lines of inquiry. Fats, as such, are not unwholesome, when not eaten in excess; we need then only to consider whether oleomargarin is as digestible as butter.

By far the best statement of the case, it may be said, against oleomargarin in this respect, is to be found in the second annual report of the New York State Dairy Commissioner for the year 1885, by Dr. R. D. Clark, chemist for the Commissioner. Many authorities are there quoted to the effect that butter is more digestible and wholesome than lard or other natural fats; and this difference is attributed to the more complex composition of the former, and especially to its butyrin; and the effect of this is supposed to be due to the ease with which it breaks up into fatty acid and glycerin; saponification is thus facilitated, and this soap in its turn favors the digestion of the other fats of the butter. The digestion of the fats consists partly in this saponification, and partly in their conversion into an emulsion; Dr. Clark performed some emulsionizing experiments with different fats and the pancreatic juice, which is the chief emulsionizing agent of the digestive liquids. Next to cod-liver oil, butter gave the finest emulsion in twelve hours, while oleomargarin still had many large globules, unchanged, left. It is fair to suppose that the finer the emulsion, and the more quickly it is made, the more readily the fat will be absorbed and assimilated and taken into circulation, and that easy saponification will also favor digestion. Dr. Clark also proved that while butter melts to a clear limpid liquid in thirty-five minutes at 100° F., the oleomargarin was but slightly changed; even after five hours, the latter was still in a semi-solid condition; this property of oleomargarin is certainly not favorable to its digestion. Thus a very good case is made out by Dr. Clark, to the effect that oleomargarin is in all probability less digestible than butter. This view is supported by the results of a comparative test of the proportion of fat absorbed by a man and a boy using butter of the ordinary kind for three days, and then oleomargarin for the same period. The difference was slightly in favor of the butter, but so slight that the writer considered that it might be neglected, except in the case of invalids or very young children. In France the first opinion of medical men, in 1872, as to the digestibility of oleomargarin was not unfavorable; but eight years later it was pronounced against in the Paris Academy of Medicine, the statement being that it could not replace good butter because, on account of the higher percentage of fatty acids, it emulsionized less easily, and was therefore less easily absorbed; but I can find no account of any actual digestion experiments in support of this conclusion, like those of Clark's just quoted, and which are of more account than any theorizing.

The question of the occurrence of germs of disease in oleomargarin is of such great importance, that it needs some little further consideration. The possibility of their occurrence there cannot be denied; and it must be allowed that the heat used in any stage of the manufacture of the oleomargarin is not sufficient to kill these germs. Dr. Clark gives as diseases that may be communicated from animals to man: consumption, anthrax, tapeworm, glanders, foot-and-mouth disease, cow-pox, hydrophobia, etc.; the etc. implies that there are still others, but the list is fearful enough as it is. Now, what evidence is there that there are any of these disease-germs in oleomargarin? Granted that they may be there; but have they ever been found there by reliable observers? Any such evidence, sound and satisfactory, would be the most damaging that could possibly be made against this food-product. The observations made by Piper and Nachtrieb lack utterly the confirmation of repetition by others; no similar observations have ever been reported since. Dr. Clark does not even refer to them. It may, therefore, be safely affirmed that there is no evidence whatever that in the oleomargarin of later years—from 1885 up to the present time—any germs of disease exist.

But good evidence of the communication of any of these diseases to man by the use of oleomargarin would be no less fatal to this food-product. Members of Congress assert that its consumption leads to insanity, Bright's disease, and ailments that undermine the strongest constitution; that it is "freighted with disease, freighted with death;" "that it spreads death throughout the country." Dr. Clark, in response to the call for cases of illness caused by oleomargarin, can only say that "We have seen many cases of sicknesss, much of it dyspepsia, during the period in which bogus butter was so freely sold without restriction, for which we have been unable to assign any cause; this cause may have been the use of artificial butter, but the deceptive manner in which it has been handled prevented physicians from ascertaining its effects; consequently we must judge by its qualities." This is a confession that up to that time—1886—and only shortly after a time when it was claimed that twenty million pounds per annum were made and mostly used in New York and New England, no case of disease nor any general specific form of disease could be pointed out as due even in the most indirect manner to the use of this food-product. A widely quoted statement to the effect that the physicians of Chicago attributed an epidemic of winter cholera to the extended use of butterine in that city, into the composition of which lard entered largely, may be taken for what it is

worth, as an exception to this statement of mine. I cannot verify or dispute it.

The Chairman of the New York Legislative Committee, from which emanated the present stringent prohibitory laws of that State, in his report on the committee's investigations, could only say in reference to the wholesomeness of oleomargarin, that sickness of various kinds may result from its use, communicated by the germs of disease that have been found in samples of it, but nowhere in the report of the committee is any evidence adduced of the occurrence of these germs. Even a single case of disease, unmistakably attributable to oleomargarin, would have been invaluable in promoting the passage of the desired law, but he could not produce it. And in another place in the report he frankly admits that "There is evidence on both sides as to its wholesomeness. Time and further investigation may be needed in order to establish a satisfactory solution of the question of trichinæ, animalcules, or germs of disease in raw animal fats and their tissues. Meanwhile, however, there is well-grounded suspicion of them." Time there has been—years of it—since that report was made public. The prohibitory law was passed, but no further investigation has been reported on the trichinæ and germ question, and the danger of disease from this cause must be regarded as unproved.

Beyond what I have given you in what has gone before, I find nothing more in the literature of the subject for the past twenty years that relates to the question of the danger to health in the use of oleomargarin, except numerous statements by scientific men of eminence in this and other countries. Morton, President of Stevens Institute; Chandler, of Columbia College, for so many years President of the New York City Board of Health; Johnson and Brewer, of Yale, both well known by the farmers throughout the country for the good work they have done in behalf of agriculture; Goessman, now and for many years past Director of the Massachusetts Agricultural Experiment Station; Atwater, of Connecticut, so well known for his writings on food products; Armsby, Director of the Pennsylvania Experiment Station; Alvord, most prominently identified with the interests of farmers for many years, and now Director of the Maryland Experiment Station—all have spoken or written in favor of oleomargarin as a food-product. It has required the courage of their convictions for many of these men to utter their opinions, and they have in many cases had only the comfort of a clear conscience to offset the abuse of the agricultural press that has been heaped upon them. Abroad I would mention particularly Lyon Playfair, "one of the most distinguished chemists and sanitary authorities of England." In his place as member of Parliament, he spoke in a very different strain from that indulged in by some of our Congressmen, when he said: "As to the relative wholesomeness of oleomargarin and butter, I do not think there is anything to choose between them. Certainly rancid oleomargarin is a nasty and unwholesome compound, but not any more so than nasty and rancid butter, which abounds in so many markets. Both are unfit for human food, although both may be well purified by well-known processes." I would like to quote more freely from his admirable speech, but lack of time forbids.

Finally, allow me to call your attention to the most remarkable absence of any reference to this food-product by the most active and efficient State boards of health in this country. If there were such dangers lurking in oleomargarin as has so many times been asserted, surely these boards of health have seriously failed in the discharge of their duty in giving so little attention as they have to the matter. A careful examination of the file of such State board of health reports as are in our library discovers almost no reference to oleomargarin.

The whole question of the wholesomeness of oleomargarin as food is summed up in my own mind about in this wise: When properly made from fresh and clean material, it differs but slightly from butter in healthfulness, and only because of its somewhat less easy digestibility, and that dyspepsia is likely to be due to a far greater extent to other causes than to this, even among those who, because of its cheapness as compared with butter, would be likely to use it largely. It is possible that it may be made from such unsuitable materials as to contain germs of disease, and that it might thus communicate disease to man, but there is no positive proof that it is now made of such materials, or ever has been, or that any disease has ever been communicated to man by its use. But the possibility exists all the same, and the only way to make it of no effect is by careful inspection of the process of manufacture by proper officials, and such inspection would be necessary in order to put the wholesomeness of the substance beyond all question.

New York being a great dairy State, and also, in the beginning, the great center of the manufacture of oleomargarin, was naturally one of the States in which special legislation began earliest. Two enactments in 1882 prohibited, first, the coloring of the product to make it resemble butter, or the sale of any such colored product; and, second, required that all packages containing any such imitation of butter or cheese should be plainly labelled. In 1884 the manufacture and sale of such imitation were forbidden in a special section of a general dairy law. This was pronounced unconstitutional by the Court of Appeals, but another slightly dif-

ferent enactment in the following year was allowed to stand. At the close of 1885, Maine, Michigan, Minnesota, Missouri, New Jersey, Pennsylvania, and Wisconsin, beside New York, had laws prohibiting the sale of oleomargarin or any kind of artificial butter made from other fats, and New Hampshire had a law that was practically prohibitory, requiring that all imitations of butter should be colored pink. California, Connecticut, Delaware, Ohio, Oregon, Rhode Island, Tennessee, Vermont, West Virginia had simply regulative laws, providing that the substance shall be sold under its own name. At the close of the year ending June 30, 1891, Maryland had been added to the list of prohibitory States, and Minnesota, Vermont, and West Virginia had joined company with New Hampshire in requiring the pink coloration of the artificial butter, while New Jersey, Massachusetts, and Ohio prohibited the sale of it only if colored in imitation of butter. Of the other States, Arkansas, Kentucky, North Carolina, Tennessee, Utah, and Washington had no enactments in regard to the matter. The remainder of the States, twenty-five in number, only required that it should be sold under its own name, and not as genuine butter. Abroad the laws are all regulative and not prohibitory.

In 1886 a national law was passed under the title of "An Act defining butter, also imposing a tax upon and regulating the manufacture and sale and importation of oleomargarin." This Act required every manufacturer to pay a license fee of four hundred and eighty dollars, and every retail dealer selling in quantities less than ten pounds to pay a fee of forty-eight dollars, and that every pound sold shall pay a tax of five cents. It was first attempted to make this ten cents, but by reduction to the lower figure the enactment was saved from being practically prohibitory. President Cleveland approved the measure on the ground that Congress is justified in making oleomargarin a subject of internal taxation; that Congress may clearly levy such taxes as will confer incidental advantages on the people, and that no industry is better entitled to such incidental advantages as may follow this legislation than our farming interests, and that the quality of the article will come under more strict scrutiny, so that only a good and clean product will be sold, and, finally, the product will be sold under its own name, and fraud and imposition will thereby be suppressed.

The constitutionality of this final enactment was decided on this ground: that when a product of manufacture is turned out so closely resembling some other product of which the manufacture is already established as not to be distinguishable from it by the senses, and is made for sale in the place of that substance, it is constitutional to prohibit the manufacture and sale of it. But if it is turned out, say uncolored, then its manufacture and sale cannot be prohibited, except on plain grounds of injury to the health of the community.

Recalling to mind some of the extravagant statements in Congress in support of this measure, and especially of the ten-cent clause of it, the comment on it by a prominent agricultural paper is appropriate, that "If oleo is as bad as it has been painted, the new law will make the Government party to the crime of permitting an unwholesome article, and is, therefore, simply and purely a compromise with the devil." I wonder how many actually believed that it was so bad?

In the case of the prohibitory law of this State, the Supreme Court affirmed its constitutionality, saying that "the manufacture of an article may alike be prohibited by the legislature, if in their judgment the protection of the public from injury and fraud requires it. The fact that the prohibited article may be innocuous is irrelevant—the sale of a mixture of pure water and milk has been prohibited." Here, again, the question of the public health is not taken into account. Of the same character was the decision of the Missouri Court of Appeals on the constitutionality of the prohibitory law there; nothing was said about the public health.

In the case of the almost frantic appeals sent out from Washington at the time that the practically prohibitory bill with the ten-cent clause was pending, it was the farmers of the country who were called upon to work upon their representatives directly, and upon the Senate through their respective legislatures, to secure the sufficient support of the bill in Congress.

Not a few protests have appeared from time to time against such legislation, even in the agricultural press. One of the most prominent dairy writers of the country, writing before the passage of these laws said: "There is no law, and there can be no law, to prevent its sale for what it is." Another, who, while he lived, was looked up to as among the highest authorities in the country on dairying, when asked if the manufacture of oleomargarin should be prohibited by law, answered: "By no means; its manufacture is as legitimate as that of butter. Its manufacture is actually a blessing. On the one hand it is suppressing the lower grades of butter, and on the other hand it makes the finer brands of creamery butter more sought after. There is nothing for the dairymen to fear in it; their safety can be insured by improving their butter product."

As to the total production in the country at any time previously to the passage of the national law, there appear to be no reliable data. It was wildly stated to be 200,000,000 pounds; it was allowed by those not interested in making the estimate too

high, that the amount may have been half as great. For the fiscal year ending June 30, 1886, it was estimated on the basis of data claimed to be reasonably sound, to be about 33,000,000 pounds. In the following year it was nearly 34,350,000 pounds, in the next year 35,664,000. During the year ending June 30, 1891, 44,000,000 pounds were produced, and a still larger output is predicted for the year ending June 30, 1892.

As to the quality of the product now, as compared with what it was in the first years, such a comparison cannot be made with any degree of satisfaction, since we have so few reliable data based on official inspection of the products. President Cleveland gave this as one reason for his approval of the national law, that the quality of the article would come under more strict scrutiny, so that only a good and clean product would be sold. But it cannot be said that this hope is justified. In the first report of the commissioner under the new law, the inspectors in some cases stated that they had examined into the character of the materials used at the factories, and found everything as it should be. But since that time I find no evidence in any of the reports that any attention is given to this matter by the inspectors.

To sum up what appears to me the fair position in regard to oleomargarin: It is a food product, unquestionably; no legislation can rule it out of the list of food products. Taken into the system it follows the same course as butter does, is changed in the same way, if not perhaps so completely; is taken into the circulation and then serves precisely the same purpose that butter does. When properly made from proper materials it is entirely harmless, except possibly when consumed as freely as butter by persons with weak digestive power.

While it is claimed by manufacturers that a good artificial butter cannot be made if fats are used that are not clean and wholesome at the start, it may not be that this is fully established. But on the other hand, it must be granted that there is no evidence that any community in which artificial butter has been used, even freely and without any official inspection or restriction, has been any the worse for its use in respect to health, either individually or collectively. These being the facts in the case, it is not surprising that many regard as unjust any legislation that prohibits the manufacture or sale of this substance, whether directly or by such ridiculous subterfuges as requiring it to be colored pink or any other abnormal color. The chief motive, nay, almost the only real, hearty motive for this legislation was that of attempting to save from pecuniary damage another industry working along in the same line.

On the other hand, oleomargarin is not butter, and it is wrong to sell it as butter, no matter how good the imitation may be; probably its manufacturers and dealers have brought all this trouble in the way of prohibitive legislation on themselves, by their attempts to sell it as butter. All over the civilized world, general or special laws exist prohibiting the selling of anything for what it is not; no one denies the equity of these laws. When a man sells oleomargarin as butter, he is violating these laws, and just in proportion to the ease with which the imitation can be palmed off for what it is not, and just in proportion to the value of other useful industries that are injured by such deceit, should be the penalties imposed on the fraud, and the efficiency of the means for its detection, so that the producer of the genuine article shall not need to go far out of his way for the means of defence. Therefore laws requiring that oleomargarin shall be sold for what it is are just laws, I care not how stringent they may be.

Furthermore, there is work for boards of health in connection with the manufacture and sale of this food product in States where these are permitted; especially should its manufacture be watched. This needs to be done at least until it has been fully established that only clear fats from animals killed in health can be used. The large license fee required of manufacturers throws the manufacture into comparatively few hands, and thus inspection is rendered more easy. Under such restrictions it seems to me that the trade in this food product might be safely left to itself—and that it might be a blessing to the community as a whole in supplying, at low prices, a savory substitute for butter, which the poorer classes have to eat, far better in quality than most of that which the poorer classes have to eat if they can get only genuine butter; and for those who can afford to pay for good butter, the opportunity to get it will be better, for dairymen will be obliged to make good butter if they make it at all.

THE NERVOUS AND MENTAL PHENOMENA AND SEQUELÆ OF INFLUENZA.[1]

BY CHARLES K. MILLS, M.D.,
OF PHILADELPHIA.

THE prominence of nervous and mental phenomena has been a striking feature of the recent epidemics of influenza. Much has been written, but mainly in a desultory way, about the symptoms of the disease referable to the nervous system, and about its nervous and mental sequelæ. The part played by the nervous system in the etiology and history of the disease has been variously interpreted. One holds that it is a "nervous disease," without

[1] Abstract of a paper read before the Philadelphia County Medical Society, January 13, 1892.

explanation; another describes it as a pneumogastric neurosis; another as a neuropathy due to ptomaïne poisoning. According to Blocq, cited by Church,[1] the primary infectious action is exerted upon the nervous system during the disorder, while sequelæ are to be attributed to secondary intoxication by ptomaïnes. Cheston Morris,[2] of Philadelphia, advances the theory that the general symptoms of influenza may be traced to a derangement of function or partial paralysis of the pneumogastric nerve, and that the affection is brought about by conditions of the atmosphere that particularly tax the cardio-pulmonary apparatus, which is regulated by this nerve—a view that, after all, relegates the disease to an atmospheric or infectious cause. Graves long ago referred the bronchial and pulmonary symptoms to lesions of the nervous apparatus of the lungs, and Blakiston regarded the disease as a disorder of the nervous system, with concomitant derangement of the organs of digestion, circulation, etc. Levick,[3] who quotes the last two authorities, holds that certain symptoms are produced when the poison is expended upon the sensorium, and certain others when its influence is chiefly exerted on the respiratory centers.

The analogies or relationships between influenza and other diseases generally recognized as belonging to the nervous system, either primarily or because of the situation of their most notable lesions, have been strongly developed by able writers, as by Levick, for example, who has even suggested that epidemic cerebro-spinal fever, or cerebro-spinal meningitis, may simply be a malignant form of influenza—a view to which he was led because of the resemblance in the symptoms of the two diseases, which differ in degree rather than in nature, and also because for three centuries the two have occurred coincidently or in close sequence.

Grasset and Rauzier,[4] in a monograph on the influenza of 1889–90, lay great stress on the enormous predominance of the nervous over the catarrhal elements in the epidemic, as indicated by the high fever, the intense cephalalgia, the marked delirium, the widespread pain, and the excessive nervous irritability. They refer to cases reported by M. Coustan, in which the entire symptomatology of the disease seems to have reduced itself to a horrible migraine.

According to Schmitz,[5] influenza is a disease of the nervous system, with secondary involvement of the heart, lungs, and digestive organs. In several hundred cases that he observed the nervous symptoms were always primary, and were in every case followed by secondary manifestations in other organs.

The briefest consideration of the subject brings forcibly to mind the fact that all diseases of infectious or toxic origin—epidemic, endemic, sporadic, or accidental—may involve any or all parts of the nervous system with a result that will be proportionate—first, to the virulence of the infecting agent; and, second, to the resistance of the individual, whether or not this be affected by constitutional predisposition or by the results of previous injury or disease. The etiologic elements may differ, but a bond of union and a close resemblance can be recognized among the effects on the nervous system of all contagious and infectious diseases, such as variola, scarlatina, diphtheria, measles, whooping-cough, typhoid fever, typhus fever, leprosy, mumps, cholera, erysipelas, puerperal fever, influenza, or cerebro spinal meningitis; of all such constitutional and diathetic affections as tuberculosis, gout, rheumatism, and diabetes; and of all such toxic agents artificially introduced into the system as alcohol, mercury, lead, arsenic, copper, and poisonous gases. These diseases, these diatheses, and these poisonous liquids, metals, and gases produce or may produce nervous and mental phenomena of the same character, differing in degree in particular cases and for special reasons.

In the course of any of the affections named there may at one time or another be present such symptoms as great mental and nervous debility, irritability, restlessness, sleeplessness, or the opposite states of torpor, stupor, hebetude, or coma; delirium; vertigo or syncope; aches and pains of all degrees of severity referred to various nerve-areas; hyperesthesia of the skin, of muscle-masses, or confined to nerve-trunks or branches; spasms, local or general, and with or without loss of consciousness; sometimes mental disturbance amounting to true mania or melancholia—in brief, any infectious or toxic disease may produce the same symptom, syndrome, or train of phenomena, as a result of the introduction into the system of an agent that directly and powerfully poisons nerve-centers, and possibly also nervous conducting tissues.

Following all infectious, diathetic, or toxic diseases, moreover, or directly springing from them, common experience teaches that we may have great nervous or general weakness; forms of insanity of the depressive type; paresis and paralysis of every grade from an affection of a single muscle to that of all the extremities, and even more; localized spasm or cramp; general convulsions;

pains in nerves, muscles, and joints; and losses or perversions of sensation.

These symptoms and conditions, which may occur at the onset, during, or after the subsidence of any infectious or toxic disease, are those that constitute the nervous features of the prevailing epidemic.

Any attempt to classify the nervous and mental phenomena of influenza must be attended with great difficulties. There are, in the first place, symptoms and conditions that, although manifested in non-nervous organs, are directly traceable to a nervous origin; secondly, affections that would be readily recognized as properly referred to the nervous system; and, thirdly, affections occurring in nervous tissues and organs, although, strictly speaking, not nervous diseases.

I will but briefly refer to the first of these classes. I wish simply to emphasize the fact that some of the most prominent pulmonary, cardiac, and vascular affections of influenza can best be explained on neural theories. Many personal observations have led me to the conclusion, not new, which has recently been well presented by Elliott,[1] of New Orleans, that the pneumonias of influenza are often due to vasomotor paralysis; that they are, in fact, forms of blood-stasis or passive congestion from vasomotor paralysis, which in its turn is dependent upon the action of the infection upon the pneumogastric centers and the nervous system in general. A distinction can be made between the true pneumonic lung and this "grip lung," as it has been termed by Elliott.

Many disorders in various parts of the body are best explained on this theory of local vasomotor paralysis, although it is not necessary to attempt to force this explanation for all. Hemorrhages, minute or even of considerable size, occurring in diverse localities, as in the retina, membrana tympani, and internal auditory apparatus, or in the skin, or in mucous or serous membranes, may be due to deficient vasomotor tonus. Brain, kidneys, liver, or pelvic organs may suffer from forms of passive hyperemia, subacute or chronic, which are in fact due to vasomotor palsy. Occasionally, we meet with cases of vasomotor disorders of the extremities, such as flushed or pallid fingers.

Even trophic affections have been observed. Wilson,[2] for example, refers to gangrene of the lungs as one of the less common complications. Abscesses of the limbs have been recorded. Grasset records two observations of eschars occurring in young subjects in the absence of prolonged decubitus. The greater tendency in surgical cases to suppuration may have its explanation in the depression of healthful vasomotor and trophic influence.

The peculiar forms of pulse, and the uncertain or perverted action of the heart, progressing in some cases to cardiac palsy and death, are in a strict sense nervous phenomena due to paralysis, partial or complete, of the inhibitory apparatus of the heart. Tachycardia and irregularity of action of the heart may remain as sequelæ.

I shall now take up those symptoms and affections that would clearly be recognized as belonging to the nervous system.

I believe, with Church, "that the infection of influenza has a marked action upon the nervous system which may give rise to immediate acute manifestations or to remote and persistent conditions; and that, in the predisposed, grippe is competent to cause marked excitement or great depression of the motor, sensory, and mental nervous apparatus."

Great nervous and mental prostration, both as an acute manifestation and as a persisting sequel, has engaged the attention and required the treatment of all practitioners. The mental depression often present as an initial symptom has in some cases been simply overpowering. In some cases it seems as though the brain-centers had been poisoned to the limits of human endurance, consciousness, however, being preserved. In other cases, even consciousness itself has been overwhelmed.

Not a few patients that suffered from influenza during the early period of the present epidemic are still victims of profound neurasthenia. I now refer to cases that are not distinctively of the melancholic type. These neurasthenics are unable to endure an ordinary amount of work; their nervous forces are soon routed; they are weak, worrisome, and unrecuperative. The cardiac weakness that has been left is undoubtedly in part the cause of this neurasthenia.

Among organic nervous diseases that have developed during the influenza, or have been left in its wake, are, in the order of their frequency, so far as my personal observation has gone, neuritis, meningitis, myelitis, and cerebritis, or various combinations of these inflammatory affections, as, for example, concurrent neuritis and myelitis, meningomyelitis, or meningo encephalitis.

Probably no single affection of the nervous system has been so common during and after influenza, and particularly as a sequel, as neuritis. Almost every variety of neuritis, as regards location and diffusion, has been recorded, and has come under my personal notice. Multiple neuritis, while not common, has not been rare; and I have seen an apparent concurrence of this affection with poliomyelitis in the same case. Isolated neuritis of almost every cranial

[1] Elliott: The Climatologist, vol. i, No. 1, 1891.

[2] Wilson: American System of Practical Medicine, vol. i, p. 870.

nerve has been recorded, with such resulting conditions as optic atrophy, loss of smell and of taste, ophthalmoplegias, both internal and external; oculo-motor, facial, and bulbar or pseudo-bulbar palsies of various types, including true pneumogastric paralysis. Several cases of specially located affections of the sympathetic ganglia or nerves have been recorded. Of the forms of local neuritis most common may be mentioned the supra-orbital, intercostal, sciatic, and plantar.

An interesting case of neuritis with a myxedema toid condition of the limbs presented herself at the Philadelphia Polyclinic recently, five weeks after a sharp attack of influenza. She was extremely weak in the legs, and was scarcely able to drag herself around. In a few days her feet and legs began to swell and to be painful, and soon became of enormous size and exquisitely tender. She has gradually improved, but still has a condition of firm swelling, from her knees to her ankles, which does not pit on pressure, and she also still has great tenderness on squeezing the feet or ankles, or in handling the nerves or muscles of the limbs. She has no cardiac affection.

The articular pain and other so-called rheumatic manifestations so numerous during and after attacks of influenza, are best explained on the theory of infectious neuritis or myositis.

The cases with articular and other pains, and with swelling, recall the endemic or epidemic form of multiple neuritis known as beri-beri, in which the chief phenomena are edema and paralysis of the limbs, with marked pain, hyperesthesia and paresthesia, followed later by anesthesia, loss of knee-jerk, and enfeeblement of electric reactions. Myositis certainly, and probably also periostitis, occur as complications or sequences of influenza, and usually in association with neuritis of some type.

Many of the reports speak of the frequent occurrence of various neuralgias. Doubtless a distinction is seldom made by observers and recorders between neuralgia and neuritis, which are or may be separate affections. Practically those cases should be regarded as neuralgic, in which pain is refered to certain nerve-lines or radiations; but in which pain on pressure, and other phenomena of neuritis, such as anesthesia, vasomotor, and trophic disorders, and even paralysis, are wanting. In my own experience the cases that could be properly diagnosticated as neuritis are by far the most common. The distinctively neuralgic pains are probably due to toxemically depressed or exhausted sensory nerve-roots or centers in the cord and bulb.

Of diseases of the spinal cord proper, occurring as complications or consequences of influenza, the reported cases are not numerous, but they are none the less important. A few cases of myelitis have been put on record by native and foreign observers —in one that I recall all four extremities were paralyzed. As would be expected, in accordance with the analogies with other infectious and toxic diseases, anterior poliomyelitis is the most common type. I have had several cases of temporary paralysis of one or more limbs, which, owing to the absence of pain and of cerebral symptoms, were apparently spinal in origin, and probably mild forms of inflammation.

Several observers have reported cases of bulbar paralysis, and one striking example of this disease, attributed to the influenza, has come under my own observation, although exactly how far the influenza was responsible it is difficult to say. The patient, a clergyman, soon after a severe attack of influenza, noticed that he was losing power in his hands, which soon atrophied. Some months later difficulty of speech appeared, and when the man came under my observation he presented symptoms of well-marked bulbar paralysis, with progressive muscular atrophy, chiefly involving the upper extremities.

In accordance with analogy, we would expect the occasional occurrence both of nuclear polioencephalitis, and even rarely cortical polioencephalitis. One or two of the few cases of probable polioencephalitis of the latter type have occurred in patients suddenly stricken with fever, loss of appetite, and other symptoms that may have been due to infection.

Priester[1] has reported the case of a man fifty-four years old, who was taken with influenza in February, and in the beginning of March was seized with extremely violent headache that resisted all medication; subsequently the patient became deeply somnolent, remaining so for four weeks; he could be aroused, but was apathetic and soon slept again. Reflexes and temperature were normal; the pulse was from 46 to 60. The patient had no paralytic symptoms, and slowly improved. The affection resembled paralyzing vertigo—what is described as a disease of the hot season. Tumor could be excluded by the absence of all focal symptoms a year before the attack. The most probable cause was a pathologic process involving the central gray matter of the third ventricle, so that the disease would be brought into close relation with polioencephalitis of the nuclear type. Kaumheimer has observed an exactly parallel case, which originated in April, and lasted into July before recovery took place.

That meningitis, either cerebral, spinal, or cerebrospinal, occurs during the progress or decline of influenza cannot be doubted in the light of the evidence that has been presented by various observers, and particularly during the epidemics of the last three years. It is, however, a comparatively rare

[1] Priester: Wien. med. Woch., No. 27, S. 1159.

concomitant or complication. Some of the facts adduced as proofs of the existence of meningitis, and some of the cases reported as examples of the disease, are clearly instances of improper interpretation. The intense cephalalgia and rhachialgia; the atrocious pains variously localized in the face, trunk, limb-nerves, muscles, or joints; the vigliant delirium, with hallucinations and delusions, sometimes assuming great gravity; the intense vertigo, with or without nausea and vomiting—these and other well-known nervous manifestations, which are so prominent in many cases at the initiation of the disease, are not necessarily evidences of meningitis, or even meningeal hyperemia. Rather are they due to an overwhelming toxemia of the nerve-centers and of the brain. Severe and terrible in character at first, they frequently pass away almost as rapidly as they came, which they would not do if they were the evidences of a true meningitis. The great prostration that remains shows that the centers of nervous energy have been subjected to a depressing influence of great virulence, not that merely enveloping membranes composed mainly of fibrous tissue and bloodvessels have been congested or inflamed. Nor is there reason why such congestion or inflammation should leave such results.

The reports of cases of meningitis must thus be received cautiously, and in some instances incredulously. They are only to be relied upon when confirmed by autopsies, or when made by competent and reliable observers.

It may also be worth while at this point to refer to this somewhat frequent diagnosis. A diagnosis of chronic meningitis as one of the sequelæ of influenza is sometimes made because of the presence of persistent pain in or on the head. Experience has led me to believe that this pain is usually neuritic rather than meningeal. Even deep-seated intracranial pain does not necessarily indicate meningitis. It may be due to neuritis, just as certainly as a pain in the hand or foot. The fifth nerve has an immense distribution within as well as outside the cranium, largely to the dura mater but also to other tissues and parts. It is a pathologic possibility to have dural neuritis without a pachymeningitis, and this is the true explanation of some pains, both acute and chronic, which are present in other diseases as well as in influenza.

The variety of meningitis most likely to be present in influenza is an inflammation of the pia-arachnoid or soft membranes—lepto-meningitis. From observations, corroborated by autopsies, I know that this affection may exist without pain; while pain of varying degrees of severity, and usually intense, is practically invariable in pachymeningitis. Lepto-meningitis, however, is not usually without pain and hyperesthesia as symptoms, but these may be absent; their presence or absence will depend upon the location, extent, grade, and complications of the meningitis.

While believing that these criticisms upon the sometimes hasty and the too frequent diagnosis of meningitis in influenza, and indeed in many other infectious and febrile diseases, are just, and can be sustained, it remains true that a genuine meningitis, sometimes of malignant type, may appear during the progress of or closely following influenza. Competent observers have reported cases of this character, and in a few instances the diagnosis has been confirmed by autopsies. The diagnosis should be based upon the signs and symptoms that would be satisfying as to the existence of meningitis from any cause; not alone on the presence of such phenomena as headache, vertigo, and vomiting, but on such more convincing manifestations as optic neuritis, and localized spasms or palsies, either cortical or of cranial nerves.

The fact that meningitis, and even the cerebro-spinal form, does occasionally occur in association with influenza, is by no means proof that this disease and epidemic cerebro-spinal fever are identical. It simply emphasizes the point that every infectious or poisonous agent introduced into the economy may produce the same or similar pathologic results in the nervous system. Largely according to the vulnerability, special or general, of certain tissues and organs, will be the preponderance of this or of that form of so-called disease—for instance, of neuritis, myelitis, meningitis, cerebritis, or of combinations of these affections. All infectious and toxic diseases present neuritis as the most common acute or chronic inflammatory manifestation, although myelitis, cerebritis, and meningitis may occur. Even in cerebro-spinal fever, as I was perhaps the first to point out, multiple neuritis is a common complication; but the infection being virulent and overwhelming, we may not only have meningitis but even meningo-encephalitis, or meningo-myelitis, with all of the concomitant malignant phenomena and permanently disastrous results.

Vertigo, like pain, is another symptom, often improperly referred to meningeal or cerebral inflammation. It is sometimes due to such disease, but occurring in influenza it may arise from other causes, as, for instance, from extravasations into the labyrinth or other portions of the auditory apparatus, or from profound cerebral exhaustion.

Müller[1] reports the case of a man fifty years old, who after an attack of influenza presented great physical exhaustion. In a few weeks his mind seemed affected and he became somnolent, so that he could be roused only with difficulty and would

[1] Müller: Berlin. klin. Woch., No. 37, 1890. Cited in American Journal of Insanity and Nervous Diseases, December, 1891.

then fall asleep again. Pain was present upon pressure over the vertebræ; the neck was rigid; the pulse was small and irregular; the skin-reflexes were diminished; and the tendon-reflexes were absent. In two weeks he began to improve. It is believed that the case was one of cerebro-spinal meningitis, such as is seen after infectious diseases.

Without entering into a discussion of their pathology or their peculiarities, I shall briefly mention a few other forms of nervous disorder, occurring during the course of, or apparently as sequelæ of influenza, examples of which have come under personal observation. Various observers have reported the occurrence of convulsions. In a few instances the convulsive habit has been established, and the patients have remained up to the time of report as cases of epilepsy. I have seen two such cases. Hystero-epilepsy and other grave hysterical phenomena have been initiated by an attack of influenza, or have recurred in cases in which the symptoms had long been dormant. Of local spasmodic affections I have seen no records; but one case of persistent clonic torticollis, with some pain and tenderness in the distribution of the spinal accessory nerve, has been in attendance at the Philadelphia Polyclinic. Two cases of facial paralysis, occurring immediately after an attack of influenza, have come under observation.

Many affections not of, but occurring in, the nervous system have been reported as complications or as sequences of influenza. These include such affections as apoplexy, due either to hemorrhage, thrombosis, or embolism. A patient at the Polyclinic, a man thirty-seven years old, a month after an attack of influenza in which he was not confined to bed, but suffered severely from headache, cough, and persistent general weakness, was suddenly paralyzed on the right half of his body, and became completely aphasic. Well-marked cardiac murmurs were present. In this and similar cases, influenza is probably causative by lighting up old endocardial trouble, or in consequence of the blood dyscrasia and general prostration that it leaves.

Various observers have reported cases of monoplegia and hemiplegia, without indicating their pathologic character.

I recently saw, in consultation, a typical hemorrhagic apoplexy in a case of influenza in a woman about sixty years old, who had previously been in fair health, and was not known to have had any disease of the kidneys or heart, although her vessels were somewhat atheromatous. Prentiss[1] has reported three cases of cerebral apoplexy occurring during the progress of influenza; one was in a man fifty-seven years of age; another in a man of eighty-seven; a third in a woman of sixty-seven. At least one of these was hemorrhagic; the other two were probably thrombotic. In cases of this character the infective agent predisposes to the occurrence of apoplexy both by the changes in the blood to which it gives rise, by its effects upon cardiac action, and by the general debility induced. Such apoplexies might occur from other depressing causes; they are to be regarded not as phenomena, but rather as accidents of the epidemic.

Uremic convulsions in patients suffering from chronic nephritis have been precipitated by an attack of influenza. It has also seemed to me that influenza has been active in lighting up latent syphilitic taint.

In one case of paretic dementia of somewhat irregular type, seen in consultation, the initial symptoms of the disorder were observed soon after recovery from a severe attack of influenza, the wife and friends of the patient, in fact, attributing the mental disorder to this attack. The probabilities are that syphilis was present, but latent, prior to the epidemic.

Purulent meningitis and brain-abscesses have been somewhat frequently noted in connection with the numerous instances of purulent otitis media.

The relations of influenza to insanity have not received much attention from writers.

The following conclusions compress into small compass so much that is valuable with reference to the relation between influenza and the psychoses, that I cannot do better than quote them. They are reported as the conclusions arrived at by Dr. Leledy, and were presented to the Medical Society of London by Dr. Savage:[1] "1. Influenza, like other febrile affections, may establish a psychopathy. 2. Insanity may develop at various periods of the attack. 3. Influenza may induce any form of insanity. 4. No specific symptoms are manifested. 5. The rôle of influenza in the causation of insanity is a variable one. 6. Influenza may be a predisposing or exciting cause. 7. In all cases there is some acquired or inherited predisposition. 8. The insanity is the result of altered brain-nutrition, possibly toxic. 9. The onset of the insanity is often sudden, and bears no relation to the severity of the attack of influenza. 10. The curability depends on general rather than on special conditions. 11. The insane are less disposed to influenza than are the sane. 12. In rare instances, influenza has cured psychoses. 13. The insane may have mental remissions during the influenza. 14. There is no special indication in treatment. 15. Influenza may lead to crimes and to medico-legal issues."

I can indorse from experience almost every one

[1] Prentiss: THE MEDICAL NEWS, August 29, 1891.

[1] Savage: Lancet, No. 3558, and THE MEDICAL NEWS, January 16, 1892.

of these conclusions. With reference to the statement that no specific symptoms are manifested, it should be said, however, that while this in a general sense is true, the most frequent type is a form of melancholia.

Active insanity has been observed at the onset of influenza and during its height, but more particularly during its period of decline and convalescence. The published cases have been recorded chiefly as instances of acute mania or melancholia. The commonest type of influenzal mental disorder, as I have just stated, is a form of melancholia or lypemania; but as this not infrequently assumes the form of melancholia agitata, it is often regarded as mania by practitioners not accustomed to differentiate the varieties of insanity. The patients are intensely depressed and emotional; they are filled with apprehensions of disgrace and ruin; they believe that they will never recover their former health; they are suspicious and delusional with reference to those that surround them; they are frequently unwilling to eat, or to rest, or to take medicine; and in some cases they have definite delusions of terrible character, for the most part hypochondriac or religious. They are frequently plagued with the thought of suicide, and sometimes make successful or unsuccessful suicidal attempts. They have been deprived by the ravages of disease of mental and moral stamina. In the majority of cases, but not in all, there is some hereditary or acquired predisposition. While, however, influenza usually gives rise to mental disorder of special type —a form of delusional melancholia—under special conditions it may be, as stated by Savage, the starting-point or exciting cause of any variety of mental disorder, such as mania, paranoia, paretic dementia, hebephrenia, etc.

K. Helweg[1] has recorded the results and action of influenza in the Asylum at Aarhus, Denmark, of which Pritchard has prepared a summary for the *Review of Insanity and Nervous Disease*, for December, 1891. The disease appeared in the asylum January 4th, a few weeks after it had first been observed in the neighborhood. Of 520 insane, 41 were so severely attacked that they were confined to their beds. The disease seemed decidedly contagious. It spread with difficulty, as the wards were divided one from another. Eight of the twenty-five wards were spared altogether. When a ward was invaded, the disease would rapidly run its course, to proceed to another. The transmission of the contagion could be distinctly observed in the sick wards to which those stricken down in the other wards would bring the disease and transmit it to patients. Seven patients had pneumonia. A relatively large percentage (six) died; four deaths were from pneumonia. The most constant pathologic lesions were extreme hyperemia of the cranial bones and membranes, the dura and the brain-mass itself in two cases presenting recent and high vascular pseudo-membranes containing small hemorrhages. The veins and arteries of the thinner cerebral membranes were greatly distended with blood; the large basal arteries were so filled with coagula that they stood out like cords, or like those of an injected specimen. The brain-substance itself was hyperemic and its consistence increased. The average weight of the brains was about the ordinary weight of those of Aarhus.

In the case of a sane nurse that died of pneumonia complicating influenza, there was great hyperemia of the brain and its membranes, yet not so pronounced as in the cases fatal in the insane. In a few cases in which influenza was accompanied by severe psychic symptoms, the condition resembled acute delirium. The symptoms are, however, transient, and seem easily controlled by antifebrin. On the other hand, in two hopeless cases of insanity, influenza had such a favorable and curative action that they may be regarded as cured. In both cases there was pneumonia.

Epidemic influenza has impaired the *morale* of the community. Lack of spirit in work, and an apprehensiveness with reference to health, business, and all matters of personal interest have been abnormally prevalent. The hysterical have become more hysteric; the neurasthenic more neurasthenic. Hypochondria has displaced hopefulness in individuals commonly possessed of courage and fortitude. In brief, certain neuropathic and psychopathic features have been impressed upon the community. We cannot afford even to dismiss entirely from consideration the bearings of the epidemic upon the increase not only of suicides, but of other grave crimes.

The use in influenza of hypnotics, narcotics, sedatives, and motor depressants is a question of particular interest in connection with the study of the nervous and mental phenomena of the disorder. The views of practitioners and writers are here decidedly at variance. Serious mental and nervous complications, or actual insanity occurring during influenza, have been attributed to the too free use of such chemically powerful remedies as phenacetin, antipyrin, antifebrin, chloral, bromides, sulfonal, and paraldehyde; and our older narcotics, such as opium, hyoscyamus, conium, and cannabis Indica, have also come in for a share of blame. Persisting conditions of nervous prostration, and chronic respiratory and cardiac neuroses, have also been charged to drugs. Undoubtedly, such criticisms have some foundation, but it remains true that each of the

[1] Helweg: Hosp. Tidende, R. 3, Bd. viii, S. 729.

remedies named has proved itself of some value in the treatment of influenza, and particularly of its nervous types. The enormous consumption of a drug like antipyrin is a practical argument both for and against its use. What Grasset has said of this remedy might with almost equal truth be said of almost any of the rest. "This agent," he says, "vaunted by some as a panacea for all the manifestations of the disease, is considered by others a remedy absurd and irrational in all cases. The truth would seem to reside between these two extreme opinions."

IN RE HYDROGEN DIOXIDE.

BY SAMUEL S. WALLIAN, A.M., M.D.,
OF NEW YORK.

THE medical press, both at home and abroad, has of late frequently devoted considerable space to discussions concerning the value of this by no means new, but quite unique and not very well understood, product of the laboratory, considered as a candidate for antiseptic, disinfectant, and germicidal honors; yet, in giving their experience, few writers have taken the pains to furnish anything like definite details as to its chemical nature and reactions, or any practical rules for testing either its purity or volumetric strength. Some years ago I had the honor to read a paper on this agent before the Medical Society of the State of New York,[1] which was listened to with somewhat less than the proverbial apathy of such over-bored annual gatherings, not on account of any unusual literary or scientific merit, but from the novelty of the subject. Very few members of the profession in this country had at that time given the subject any attention whatever, and very many are still unaware of the great value and prospective importance of this as yet unofficinal preparation, in its possible relations to hygiene, prophylaxis and therapeutics. The popular and pharmaceutically prevalent name, *peroxide of hydrogen*, under the chemical nomenclature of to-day is a palpable misnomer and ought to be summarily dropped. It will, doubtless, cling to the product until manufacturing chemists cease to use it on their labels. The compound is a dioxide or binoxide—water being a monoxide—of hydrogen. It is, therefore, *oxidized water*, French authorities still retaining the name "*l'eau oxygenée.*"

The chemical affinity artificially induced between water and the extra equivalent of oxygen, which transforms it into hydrogen dioxide, is not a strong one, but is rather easily broken up by a variety of comparatively slight causes. Hence the proverbial instability of the product. In a pure or, rather, undiluted state, it can scarcely be handled at all, the slightest cause, such as moderate elevation of temperature, agitation, metallic contact, and other accidental and apparently trivial agencies precipitating its decomposition into water and free oxygen, sometimes with explosive violence. By such decomposition it is found to yield 475 times its own bulk or volume of liberated oxygen. Pure, undiluted hydrogen dioxide is, therefore, called 475 volumes strong, and the strength of any solution or dilution of it is estimated according to the volumes of oxygen it will yield when entirely decomposed. Practically, it is found that a solution stronger than from 3 to 4 per cent. (about from 14 to 19 volume) is as strong as can, with our present chemical knowledge, be made reasonably stable. In a therapeutic sense it is quite as strong as is ever required—in fact, even this strength needing to be much further diluted for most clinical uses.

The market is now tolerably well supplied with indifferently good and wretchedly poor varieties, a really ideal product being hard to find. It would seem that as the article has increased in popularity manufacturers have grown either careless or mercenary, and have allowed their product to deteriorate in quality. Competition, it would appear, has not yet reached a stage in which quality is of greater moment than quantity; but as the profession learns to discriminate, the inferior varieties will fall into deserved disrepute and be driven from the market. For the most part the current medical journal literature on the subject is so transparently instigated, or at least influenced, by "trade" bias that it commands comparatively little professional confidence, and many who have been theoretically convinced that the article itself has intrinsic therapeutic value have been discouraged from continuing its use on account of the difficulty of procuring a preparation possessing the requisite degree of purity and stability. In a purely economic sense, instability is a prime obstacle to the general introduction and ultimate popularization of this article in medical and surgical practice. To be always trying to remember the stereotyped precautions of tight corking, cool storage, and seclusion from light, is always irksome and frequently impracticable; while to find, at a critical juncture, too late for rectification, that a quondam fifteen-volume solution, from having been set aside for a few weeks, has degenerated into a three-volume or five-volume solution, is not only very aggravating, but in all probability compels a resort to less satisfactory substitutes. To the painstaking and inquiring surgeon this is a loss, not only of substance but also of opportunity. If to its delusive instability is added a decidedly irritating quality from retained impurities, it is little

[1] Trans. N. Y. State Med. Soc., 1885, p. 94–99.

wonder that many practitioners and impatient experimenters have almost wholly abandoned its use.

The commonest impurity noted in samples of H_2O_2 is hyperacidity. The pure product itself has a slightly acid reaction, reddening sensitive litmus paper; but the presence of free acid in appreciable quantity is a serious fault, whether the agent is to be used internally or externally. Most manufacturers purposely acidify the solution, and they do this on the theory that it is necessary in order to secure a stable article. This theory is, in reality, a chemical absurdity and delusion. Every reflecting chemist must admit that the presence of free acid in any compound solution is a menace to the permanency of its chemical composition, especially if there be present at the same time traces of earthy or mineral salts. Again, if these salts be present in any such solution, then a certain percentage of free acid becomes a necessity in order to prevent their precipitation. In any solution containing both mineral compounds and a free acid or acids, the inevitable tendency is to further chemical reactions and a resultant change in the chemical relations of the solution. This may be an unwritten law as regards text-books, but it is based on the general law which underlies all chemical facts. Thus, the salts of barium, incident to its manufacture, when not thoroughly eliminated from a given sample of hydrogen dioxide, call for a certain proportion of some free acid, in order to render the solution clear and free from a tendency to unsightly deposits. Some manufacturers resort to various expedients to render their product unusually brilliant and attractive in appearance. Sulphate of aluminium is the least harmful, and oxalic acid the most objectionable, of the many contaminations used for this purpose.

Until manufacturers of this compound cease to resort to laboratory subterfuges to cover up the shortcomings of their wares, we shall continue to encounter impure, unstable, and irritating preparations, notwithstanding the fact that they may be widely advertised and loudly labelled "medicinal," "strictly standard," "chemically pure," etc. Dr. B. W. Richardson, who has done more than any other writer to make known the valuable properties of H_2O_2, now insists[1] that acid, and otherwise impure solutions, are no longer tolerable—in other words, that the chemists must give us a genuinely neutral product, and one that will not deteriorate as to volumetric strength from other than extraordinary causes. This is not an unreasonable demand. Chemistry is a rapidly progressive science. Our synthetists fabricate quinine, saccharin, and an endless list of antiseptics and antipyretics from simple coal-tar. Our analysts split the most obscure ptomaïnes, glucosides, and alkaloids into their ultimate elements. Why should they blunder, or be only partially successful, in their efforts to combine the two commonest elements in nature?

In this connection it is no exaggeration to say that those manufacturing chemists who essay to make peroxide of hydrogen, and who are so eager to control and extend the trade in this product that they lose sight of the maxim, *In medicine only the best is good enough*, will learn, too late perhaps, that they have ruined their own market. In other words, if this bland but unique and powerful agent is to become widely known and permanently popular with either physicians or surgeons, its promoters and fabricators must cease to rely on "chemically pure" label assertions, and give to the profession a uniform preparation that is at once practically non-acid, of definite and reliable strength, and that can be retained, without rapid deterioration, under ordinary office temperatures and conditions.

This unquestionably involves the most exact manipulation and an unusual degree of chemical vigilance; but it can be done, since it has been done, and the perfect and finished product is certainly worthy the pains. The spirit of the profession is growing intolerant of anything short of the best results that pure chemicals, trained knowledge, and the most rigid accuracy in manipulation make it possible to produce. There is quite enough inaccuracy and uncertainty in the practice of medicine without any crudity or carelessness in the matter of pharmaceuticals.

To test any sample of hydrogen dioxide with sufficient accuracy for all practical and clinical purposes requires but little apparatus and a modicum of chemical tact. Every physician can make his own tests with little trouble and less expense. The requisites include a few test-tubes; a pipette holding, or at least graduated to measure, 1 c.c.; a cylindrical graduate, marked in c.c.; a glass or porcelain bowl, with a capacity of a pint or more; a small glass rod, or piece of glass tubing, for stirring; strong aqua ammoniæ, phosphoric and sulphuric acids, and a standard solution of permanganate of potassium, one part to 250 of water.[1]

Certain preliminary tests can be promptly made by the aid of the senses, without any apparatus. Thus, on opening a fresh sample of the article, if the cork be ejected with force, as if the bottle contained soda-water or champagne, it is proof positive that the contents are in a state of decomposition, and it is *prima facie* evidence that the sample contains either

[1] London Lancet, March, 1891.

[1] It is directed that 1.852 gram of permanganate be dissolved in 500 c.c. of water, which corresponds with 1 part in 270, and will, of course, indicate a proportionately greater strength in any sample tested.

free acid or some form of impurity, or both. Holding the bottle to the light, the constant rising of minute bubbles of gas to the surface will confirm the foregoing evidence, and indicates decided instability. The presence of certain free acids will be evident to the sense of smell, but particularly so to the taste. Pure H_2O_2 is not distinctly acid to the taste, but imparts a sense as of metallic contact, or of mild galvanic action. By comparing several samples the differences will be very apparent. One liter of a fifteen-volume solution should be entirely neutralized by 6 c.c. of a 10 per cent. normal solution of ammonia of 20° Baumé. If more than this is required to prevent decided reddening of blue litmus paper, either free or combined acid is present.

The volumetric test is as follows: To half a pint or more of water contained in the glass or porcelain vessel mentioned, add twenty or thirty drops of sulphuric acid; then with the pipette add exactly 1 c.c. of H_2O_2, stirring the mixture thoroughly with the glass rod. Fill the cylindrical graduate (which should read downward) up to zero, with the standard solution of permanganate of potassium, and pour from it slowly into the bowl of accidulated water containing the H_2O_2 to be tested, stirring the mixture rapidly until the color of the permanganate is no longer discharged, taking pains not to add more than a drop or two beyond the exact quantity required. The number of c.c. of permanganate solution used indicates the volumetric strength of the sample. Thus, if in a given case 10 c.c. of permanganate solution is decolorized by 1 c.c. of H_2O_2, the latter is said to be of ten volumes strength. In other words, such a sample, on being completely decomposed, will yield ten times its own bulk or volume of free oxygen.

To detect the presence of barium and other earthy compounds, which, as a rule, are but imperfectly removed by even the most reputable manufacturers, here or abroad, proceed as follows:

To half an ounce or more of H_2O_2, in a perfectly clean test-tube, add a few drops of phosphoric acid, to favor perfect solubility. Shake well, and then add ten or fifteen drops of strong aqua ammoniæ. On agitating the mixture effervescence will occur, and oxygen will be somewhat rapidly liberated. If there be appreciable quantities of earthy salts in the sample it will turn decidedly milky, and on standing will precipitate a flocculent deposit, which will be more or less abundant, according to the degree of impurity. This test will be more thorough and reliable if the solution be heated nearly or quite to boiling-point before adding the ammonia. If neither a cold nor a hot solution thus treated shows the cloudiness or deposit, it may be considered free from any notable quantity of chemical salts. This test is by no means quantitatively accurate, but it answers for practical purposes, and applies equally well for the detection of nitrates, sulphates, phosphates, or chlorides.

As a practical application of the foregoing, I have before me five different brands of the so-called "peroxide of hydrogen." Four of them are of American and one of German manufacture. Three of them claim to be "chemically pure," and fifteen volumes strong. One is marked ten volumes, and one makes no claim as to strength or purity. To secure exact fairness in the test, all the samples were freshly procured.

No. 1 bears the foreign brand, is put up in an amber bottle, and marked ten volumes. On releasing the cork it is ejected with moderate force, and fine bubbles of gas are seen to rise. The permanganate test indicates a strength of eight and a quarter volumes. The ammonia test, cold, throws down an abundant flaky deposit, as if one had added tincture of camphor to cold water.

No. 2 is contained in a long-necked bottle, similar to an Apollinaris bottle, the sample having ample space above the liquid, which space, the label asserts, is "necessary for expansion." It is marked "fifteen volumes, medicinal." On releasing the strongly wired-down cork it is forced out with a distinct report, and effervescence is brisk and constant. The taste is sharply acid, and holding a teaspoonful in the mouth for a time fairly sets the teeth "on edge." The permanganate test shows thirteen and a half volumes, and the cold ammonia test instantly changes the previously clear and beautiful solution into an opaque, milky fluid, which soon throws down a copious, flocculent deposit.

No. 3 is contained in a common amber glass bottle, full to the neck, and claims to be fifteen volumes in strength, and "free from hyperacidity and earthy salts." There is no force behind the cork, and the appearance of the liquid poured out into a clean test-tube is not as brilliant as the last-mentioned sample. The taste is metallic, but not acid, although the sample reddens sensitive litmus. The permanganate test shows seventeen volumes strength, and even on heating the solution the ammonia test causes no perceptible cloudiness. It is apparently an unexceptionable product, which proves that there is no insuperable reason why all the others should not be equally good.

No. 4, contained in amber glass, bears the imprint of a heavy and highly reputable wholesale drug-house, but claims nothing as to volumetric strength, purity, or medicinal qualities. It tests barely one and a half volumes, and contains a marked percentage of free acid and of chemical salts. It is the poorest, not to say vilest, of all the samples tested.

No. 5, put up in flint glass, ejects its cork with

force, and while it is a beautifully clear and brilliant preparation, is sharply acid to the taste; it claims to be a "standard" solution, fifteen volumes strong, and tests but twelve volumes. The cold ammonia test produces no milkiness, but on heating the solution a slight cloudiness appears. This sample seems to be fairly good, except that it decidedly lacks stability.

Thus it will be seen that there is a wide and seemingly inexcusable margin of difference between these various samples, but two of them being passably good, and but one of them bearing out the claims contained in the attached labels and circulars. That anything like uniform or satisfactory therapeutic results can be expected by an indiscriminate use of these several brands is absurd. On the contrary, it is surprising that so many physicians and surgeons have been able to report favorably concerning the use of an agent that averages so bad a record in the direction of careless or unscientific preparation.

THE USE OF GOLD AND MANGANESE IN TUBERCULOSIS.

BY O. H. MERRILL, M.D.,
OF CORINNA, ME.

THIS report is based upon five months' experience in the use of hypodermatic injections of gold and manganese in cases of pulmonary tuberculosis. Ten patients have now been under observation for a sufficient length of time to enable at least a provisional opinion to be formed as to the value of this method of treatment, as advised by Dr. Blake White. Other cases, in which only a few injections were made, or which, for some cause, could not be followed, will not be considered here. Over 350 injections have been given, of which one patient received ten, another fifty-eight, while the others had between thirty and forty each. The rules laid down by Dr. White in his original publication have been followed as closely as possible, and it may be said that, in general, his statements have been confirmed. The use of the remedy does not require any special skill, and is not attended by any particular danger, if proper precautions and care are taken.

The injections were made in the arms and legs with an ordinary hypodermatic syringe provided with a very fine needle. No abscess has been caused, and only occasionally has pain or swelling followed. In only one case was there any unpleasant "reaction," namely, increased cough, with bloody expectoration. This, however, was slight, subsided in a few hours, and did not reappear on further use of the remedy in slightly diminished doses. The patients have all followed their usual occupations while undergoing the treatment. For the sake of brevity, the detailed histories of the cases will not be given. The diagnosis was established beyond a doubt by modern methods. Before beginning the injections, all the patients had been treated for some time, with rather indifferent success, by means of special diet, hygiene, creasote, and in a few instances, cod-liver oil. These various measures were also continued during the period in which the injections were used.

The first patient to receive the gold and manganese treatment was a machinist, twenty-five years of age, with incipient phthisis.

In spite of six weeks of active treatment, there was an evening temperature of 99½°, a pulse of 84, and considerable cough. As these symptoms showed the usual tendency to persist, it was decided to use the injections. In less than three weeks every symptom had disappeared, and now, four months afterward, he is apparently well. He declared that the injections cured him, but, of course, the declarations of patients can have little weight in such matters.

In the case of a woman, thirty-two years of age, with advanced disease of one lung of eighteen months' standing, the remedy seemed to arrest her downward course very promptly. After two months of faithful use an intermission of a fortnight was ordered, at the end of which time she returned much worse and begged to have the remedy administered again. Her request was granted, whereupon she rapidly improved once more. There seemed in this case to be some probability that the special treatment really had the good effect that she attributed to it.

The other eight patients were in the first stage of pulmonary tuberculosis, with distinct, though not extensive, consolidation of some part of one lung. The improvement was well marked in every case after from ten to twenty injections had been given. Appetite, weight, pulse, temperature, cough, and sweating all showed changes in the right direction. Several of these patients declare themselves well, and refuse further treatment. That they are not well is shown by a slight elevation of pulse and temperature in the evening, by a slight morning cough, and by the occasional presence of a few bacilli in the scanty sputum. These symptoms, together with a certain degree of dulness on percussion, make it sufficiently plain that further treatment is needed. It must be admitted, whatever the final results may be, that the changes in their condition have been remarkable and altogether unexpected. That most of them will relapse seems highly probable from the fact that they have not sufficient intelligence to continue systematic treatment, and from the fact that owing to lack of means they cannot have the benefit of favorable climatic influences. What the result might be with continued medical care in

a suitable climate cannot, of course, be definitely stated.

The wild and baseless announcements that have had premature delivery during the past year show how difficult it is for even well-trained minds to draw correct conclusions in regard to therapeutics. They show, furthermore, that proclamations from the laboratories may as well be tested clinically before acceptance.

In attempting to form a correct opinion in regard to the value of this mode of treatment, reliance is placed chiefly, but not entirely, upon the results obtained this year with the combined treatment as compared with the results obtained during the past ten years with an entirely similar series of cases treated without the injections. This comparison is very favorable to the new treatment. An improvement that required six or eight months to bring about in former years, has been obtained this year in as many weeks. Symptoms that were formerly very obstinate, and that were removed with the greatest difficulty, have this year yielded quickly. One of the most gratifying effects of the remedy was seen in the increased appetite that sometimes manifested itself within a week—nearly always in two weeks. Although, on account of the small number of cases treated and the short time they have been under observation, it is impossible to make any complete demonstration, yet it seems probable that, after all the deductions that strict logic requires have been made, the remedy has considerable power to ameliorate the condition of tuberculous patients, and in incipient cases, perhaps, to do more. While we have here no specific, we have a remedy that, when used carefully in connection with other means, is capable of doing excellent service, thus constituting a distinct advance in the therapeutics of tuberculosis.

CLINICAL MEMORANDA.

A CASE OF TUMOR OF THE MID-BRAIN AND LEFT OPTIC THALAMUS.

BY JAMES HENDRIE LLOYD, M.D.,
PHYSICIAN TO THE NERVOUS AND INSANE DEPARTMENT OF THE PHILADELPHIA HOSPITAL, TO THE METHODIST EPISCOPAL HOSPITAL, AND TO THE HOME FOR CRIPPLED CHILDREN.

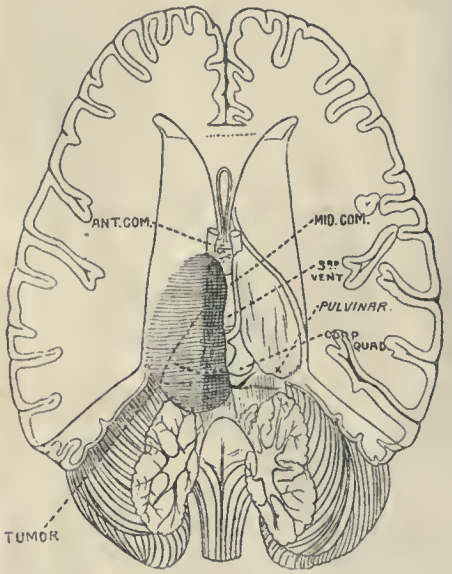
THE patient whose case I report was admitted to the Philadelphia Hospital on May 13, 1891. A very brief and imperfect history was obtained from his sister. They were Italians, with very little knowledge of English. C. B., male, aged twenty-eight, Italian laborer, was taken ill six weeks before admission to the hospital. His first symptom was paralysis of the right arm; fifteen days later he complained of severe headache on the left side; at the same time his left eyelid began to droop. No other details of any importance could be obtained from the sister.

Condition on admission. The patient's attention could be attracted, but was held with difficulty. This hebetude continued throughout the case, toward the end deepening into a light coma. The left third nerve was paralyzed, as shown by ptosis and external strabismus. The pupil was immobile, but at this time not dilated. The right arm was completely paralyzed; the right leg was paretic, but not completely paralyzed, as the patient, by repeated urging, could be induced to move it. The left arm and leg were not paralyzed and never became so. The patella-reflex of the left leg, however, was exaggerated and there was slight ankle-clonus. Neither of these were present on the right or paralyzed side. The case thus presented a crossed paralysis, the left third nerve being involved, with right brachial monoplegia and right crural monoparesis. The face and tongue were not paralyzed on either side—in fact, from beginning to end no paralysis of the fourth, motor branch of the fifth, the sixth, the seventh, or any other cranial nerve than the third was observed. The patient chewed his food mechanically and swallowed without difficulty.

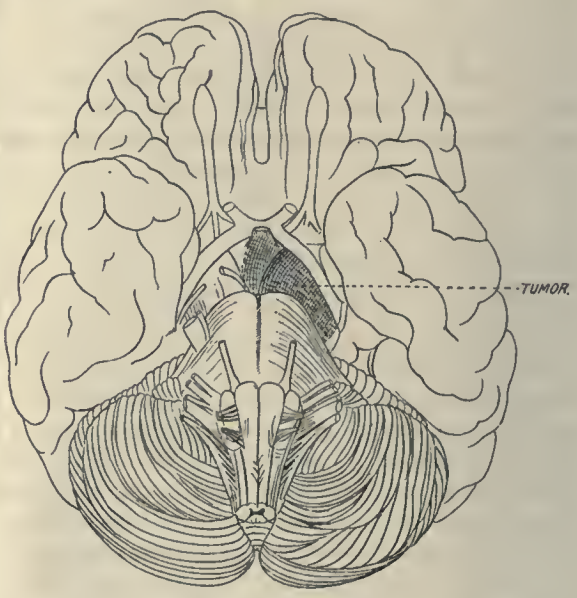
An Italian interpreter on one occasion said that the patient's speech was not "straight," but this defect was apparently not a true aphasia. The patient vomited occasionally, but vomiting was never a marked symptom. The bladder was not paralyzed. The sensory tests were not at any time satisfactory, owing to the patient's hebetude. Some interesting observations of a rather unusual kind, however, were made. There was no apparent anesthesia of either side, so far as the patient's mental condition allowed of a test. There was, however, an active reflex to sensory irritation. This reflex was free on the left side and was excited by irritation of the skin of the right leg; in other words, there was a transmitted reflex on the left or unparalyzed side from sensory irritation of the right side. Irritation over either the right or the left eye caused a reflex movement in the left or unparalyzed leg. The reflex to painful impressions was more marked in the upper part of the face than in the lower part of the face and showed itself by jerks of the arm and leg. The patient's hebetude gradually increased; he complained of pain in his head, and held his hand to his head as if in pain. Occasional vomiting was noted. He was very restless and delirious at night. Examination of the urine showed a very slight trace of albumin. At the end of the first week the patient had some difficulty in swallowing; his right leg became more paretic, and he could be aroused with difficulty. This general condition, continued, with increasing hebetude, occasional vomiting and constipation of the bowels. The paralysis of the third nerve and of the right arm and leg continued unaltered. The left pupil became more dilated. The right third nerve never became involved, which, considering the site of the tumor, is rather remarkable. Later, the right face became possibly a little flattened. Three weeks after admission conjunctivitis in the right eye was noticed, with increased lachrymation, but the movements of the eye were unimpaired. Sensory tests of the right eye were not satisfactory. It was thought, however, that the conjunctivitis may have been neuroparetic in origin, as there seemed to be loss of sensation of the conjunctiva of this eye. There was also an abrasion of the conjunctiva of the right eye over the lower part of the cornea. The eyes were

washed with a solution of boric acid and eserine. Two days before death the pupil of the right eye was contracted to a pin-point, while the pupil of the left eye was much dilated. Just before death the patient had a clonic spasm of the left leg. He died on the twentieth day after admission.

Autopsy. The autopsy revealed a tumor of the left optic thalamus and the mid-brain, involving the left cerebral peduncle. The left cerebral peduncle was



Tumor, involving left optic thalamus and left half of mid-brain. (Seen from above.)



Tumor, involving left crus and extending forward and inward, involving and effacing corpora mammillaria.

enlarged and the left third nerve was displaced by the growth. The right peduncle and the right third nerve were normal. The tumor extended forward, involving and obliterating the corpora mammillaria. The optic tract was slightly flattened and broadened. On laying open the brain-axis, by carefully removing the corpus callosum and the arch of the fornix, the tumor was seen to extend forward and to involve a large part of the left optic thalamus, which projected far across the third ventricle; it also projected up into the lateral ventricle. The aqueduct of Sylvius was pervious. On section, the growth was seen to be a soft, highly vascular, infiltrating tumor. A section was prepared by Dr. Stengel, and the growth was found to be a glioma.

It seems impossible for this tumor not to have involved the sensory tracts to a greater extent than was demonstrable at the bedside. For instance, the patient probably had had hemianopsia. Careful tests were made to detect this condition, without satisfactory results, owing to the impaired mental condition—so, too, the tests for tactile and painful impressions could not be relied upon. The prominent symptoms were the crossed motor paresis, the headache and hebetude, increasing to coma. It is especially notable that the patient at no time had an epileptic convulsion, and that the vomiting was infrequent and not characteristic.

Temperature. The patient had a remarkable course of subnormal temperature, the lowest point reached being 95.4°. The temperature was subnormal for twenty days, with two exceptions, when it rose to not quite 100°. There was a difference between the temperature of the two sides, the temperature of the right or paralyzed side being usually from one and a half to two degrees higher than that of the other. Three days before death the temperature began to rise; just before death it registered 106.1°. I have noted subnormal temperature in one other case of brain-tumor. There was no vasomotor paralysis, unless the difference in in the temperature of the two sides indicated such. There was no unilateral sweating. The bladder-symptoms, as involuntary passage of urine, could be explained by the patient's mental condition.

A diagnosis of tumor of the left cerebral peduncle was made at the first examination.

I am indebted to Dr. Frances S. Janney, resident physician, for careful notes of the case.

A PECULIAR CASE OF PROBABLE PERFORATION OF THE APPENDIX VERMIFORMIS.

BY M. ROSENHEIMER, M.D.,
OF MILWAUKEE, WIS.

ON August 9, 1891, I saw Max R., aged fourteen years, of German parentage. He had had several loose passages, after which pain developed in the umbilical region. There was marked tenderness in the ileo-cecal region, vomiting, and considerable tympanites. The temperature was 99.5°, and pulse 110. Not being able to come to any definite conclusion, I administered a dose of morphine, which afforded relief. On the following morning, the condition of the boy being about the same as on the previous day, I ordered thirty grains of calomel, in divided doses, to be followed by a dose of castor oil, if the bowels did not act in six or eight hours. In the afternoon of the same day, the bowels had not moved;

there was considerable pain, and tympanites was greatly increased. I gave an injection of warm soap-water, bringing away a small quantity of light-yellowish fecal matter. Vomiting being now quite obstinate, I gave small doses of morphine and belladonna.

I made a diagnosis of bowel-obstruction, and asked for counsel. Dr. Earles saw the patient with me, and concurred in the diagnosis. The parents were informed of our conclusion, and an operation was proposed. They consented, but, as a last resort, several doses of compound jalap powder, each of one dram, with five grains of calomel and one-quarter grain of elaterium, were administered, with no result.

On the following morning the patient was removed to Trinity Hospital, and prepared for operation. However, just previously to the time set for the operation, he went to stool, and had a copious liquid movement, with considerable relief of the pain and tympanites. He was ordered magnesium citrate one dram every hour for six hours. He had several more liquid movements and felt easier, with decided tenderness, however, still present in the ileo-cecal region. He returned home. I saw him again on the following day. His pain had increased and his temperature was 100.5°, pulse 120. He received small doses of anodynes, and his condition not improving, a collection of pus was suspected, and the propriety of its evacuation suggested to the parents. After some hesitation, their consent was granted. At about this time, another medical gentleman was incidentally called in, who pronounced the case one of peritonitis, and advised a radical change of treatment. His advice, however, was not accepted, and on the following day, the patient having again been removed to the hospital, I made an incision over the cecum, and when the peritoneum was reached a hypodermatic needle was inserted. Pus having been found, an opening was made, and about an ounce was evacuated.

The pus had no fecal odor, and was confined in a cavity in which neither foreign body nor the appendix was found. Drainage was provided for and an antiseptic dressing applied. The patient did well until the fifth or sixth day, when there was a reappearance of the symptoms that had existed—obstruction, pain, tympanites, elevated temperature, and accelerated pulse-rate. The pain was localized in the hypogastric region, about an inch to the right of the median line. The boy was anesthetized, an incision was made and about two ounces of fecal-smelling pus were evacuated. A large drain was and the patient was put to bed.

He again did well for a week and we began to consider our troubles over, when the old symptoms reappeared, the pain being now localized in the left groin. Unyielding constipation again existed and there was great tympanites. The temperature rose to 102.5°; the pulse was 144 and weak. The pain was severe, and collapse seemed imminent. The patient was given hypodermatics of morphine and was vigorously stimulated. Magnesium sulphate was also administered every two hours.

On the following day (Sunday), two weeks and four days after the first operation, the condition of the boy having somewhat improved, he was again anesthetized and an incision was made, evacuating about one ounce of pus, having no fecal odor. At the same time the middle wound was dilated, and we tried to force water from the old into the new opening, but not the slightest communication existed.

The patient reacted well from the third operation and has steadily improved up to date (October 1st), at this time being completely restored to health.

REMOVAL OF TUMORS OF BOTH OVARIES.

By ALEXANDER FULTON, M.D.,
OF PHILADELPHIA.

THE patient was Mrs. E. H., of Minneota, Minn., who came to Philadelphia to have the operation performed. Several days after her arrival, which was on the 3d of last October, after a continuous journey of two thousand four hundred miles, her symptoms were such as to imperatively demand the operation, which was done on October 13th. Observing thorough antiseptic precautions, I made an incision about three inches in length, and in depth to the aponeurotic tissue. When hemorrhage had ceased, I placed the woman on her left side and made an opening into the peritoneum. There was now a great gush of ascitic fluid. The peritoneum was incised, and a tumor of the right ovary presented. I tapped the tumor in several places, but it was still so large that I had to extend the opening four inches more. The tumor was free, and, bringing it through the opening, I transfixed the pedicle with carbolized silk and excised the tumor, which weighed thirteen pounds.

The tumor of the left ovary presented grave operative difficulties. It also had to be tapped in several places, and even after this it was of enormous size. It was adherent to the walls of the abdomen, and to the intestines, and its pedicle was very thick and contained large vessels. I detached the adhesions with my finger and the scalpel, taking great care to cut toward the tumor. I then transfixed the pedicle as in the case of the right ovary. All this time the woman was on her left side, an assistant holding the intestines in the cavity with his hands. There was but little fluid in the cavity, which I swabbed out with a small antiseptic sponge, and, without irrigation, I turned the woman on her back again, closed the wound by suture, dusted it with iodoform, covered it with sublimate gauze, padded it with absorbent cotton, and bandaged it moderately tight. Only liquid food was allowed for about a week, viz., milk, beef-tea, and brandy. Neither the bowels nor the bladder called for interference, as they moved nicely of their own accord. There was no hemorrhage or rise of temperature, and only slight increase of the frequency of the pulse. There seemed to be complete union on the tenth day; but, as the sutures caused no trouble, I permitted them to remain until the fourteenth day, when I removed them and applied an abdominal supporter, and allowed the patient to leave her bed. She has been able to get up ever since, and at the present writing has fully recovered. The tumors and fluid weighed seventy-three pounds. Immediately after removal, the tumor of the right ovary weighed thirteen pounds, and that of the left nine pounds.

The history of this case case will afford valuable information as to the detection of ovarian tumors. About six months ago this woman observed a small lump about the size of a hen's egg, on the left side. A few days after

its appearance there was a circumscribed swelling, so that the lump could not be discerned, and several weeks afterward the swelling extended over the entire side. Thus far she experienced only slight soreness. About three weeks afterward she noticed a small lump on the right side; it also was movable, and swelling similar to that upon the left side ensued, during which time she for several days suffered excruciating pain. This swelling continued until it became as large as that upon the left side, so that the abdomen attained an enormous size.

Mrs. H. is thirty-eight years of age, the mother of one child, a girl five years of age. She is a slender-built woman; in health her weight never exceeded one hundred and thirty-five pounds.

MEDICAL PROGRESS.

Successful Trephining for Basal Hemorrhage.—SMART (*British Medical Journal*, No. 1614, p. 1204) has reported the case of a woman, forty-three years old, in which, following a blow upon the right parietal bone, the face became drawn to the right. There was no ptosis, no ocular deviation; the pupils were of moderate size, nearly equal, and they reacted fairly well to light; but there was left lateral hemianopsia. Motility and sensibility were impaired upon the left side of the body. Coma, with Cheyne-Stokes respiration, developing, two trephine openings were made, one at the seat of injury, the other a little anteriorly and inferiorly. There was free hemorrhage from the membranes, but no cause for the symptoms was found within reach of the director or finger. By exclusion, the original diagnosis of a right basal lesion appeared to be confirmed. At once, when the dura was incised, the breathing improved, the relief of pressure and tension being indicated by the occurrence of cerebral hernia. Subsequent improvement was progressive, the hemiplegic symptoms in some degree, however, persisting. A year after the accident there had been no relapse.

Aneurism of the Renal Artery.—OESTREICH (*Berliner klin. Wochenschr.*, No. 42, 1891, p. 1042) has recorded two cases of aneurism of the renal artery. One occurred in a woman, fifty years old, who, three months before death, had had an apoplectic seizure. Twelve days before death intermittent hemorrhage from the bladder set in. There were severe pains in the abdomen and a tumor could be felt in the situation of the left kidney. A diagnosis of malignant neoplasm of the left kidney was made. At the autopsy, in addition to several areas of softening in the brain, an aneurism of a branch of the left renal artery was found. The surrounding retroperitoneal tissues were infiltrated with blood, and the pelvis of the kidney was filled with coagula.

In the second case, which occurred in a young man who died of multiple embolism in association with malignant endocarditis, the aneurism involved the right renal artery and had occasioned no symptoms.

Successful Trephining for Abscess of the Temporal Lobe.—At a meeting of the Berlin Medical Society, BAGINSKY and GLUCK presented a five-year-old girl, in which, following the introduction of a pea into the left ear, suppurative otitis media, with perforation of the tympanic membrane, developed. In the course of a few weeks the pulse became slow and irregular, while headache, retraction of the abdomen, twitching of the extremities, and somnolence appeared. Subsequently the left pupil became smaller than the right, though both reacted to stimuli. There was no derangement of vision and no paresis of the upper extremities. The symptoms became threatening; the head was trephined; an abscess was found in the left temporal lobe. A little more than three ounces of pus was evacuated. The cavity was packed with iodoform gauze. The subsequent course of the case was uneventful, recovery ensuing.

Chlorine in Typhoid Fever.—YEO (*Lancet*, Nos. 3528 and 3529, 1891) has recommended free chlorine as the best agent for the antiseptic treatment of typhoid fever. Forty minims of pure hydrochloric acid are added to thirty grains of potassium chlorate in a flask and chlorine permitted to generate. In two or three hours water is gradually added, and the tightly closed flask is thoroughly shaken. Then sufficient water is added to make ten ounces. The result is an almost perfect solution of chlorine. To twelve ounces of this solution are added from twenty-four to thirty-six grains of quinine hydrochlorate and an ounce of syrup of orange-peel. In accordance with the severity of the case, an ounce of the solution may be administered two, three, or four times a day.

Gastrostomy in Stricture of the Esophagus.—At a meeting of the Glasgow Medico-Chirurgical Society, KNOX (*Glasgow Medical Journal*, 1892, xxxvii, 1) presented a man forty-eight years of age, who for seven months had had progressively increasing difficulty in swallowing, and loss of flesh. On examination, a stricture of the lower portion of the esophagus, impassable to a bougie, was found. As it was feared that the obstruction would ultimately become complete, gastrostomy was performed, the stomach first being sutured to the abdominal parietes, and, after an interval of a week, incised. Not only was it an advantage to be able to successfully nourish the patient through the artificial opening, but it was found that as a result of functional rest swallowing became considerably easier.

Thyroidectomy in Exophthalmic Goiter.—CAIRD (*Edinburgh Medical Journal*, September, 1891) has reported the case of a man, twenty-five years old, with a large cystic goiter, palpitation, dyspnea, dysphagia, protrusion of the eyeballs, and increased frequency of pulse, in which, a year after excision of the large cyst and the right lobe of the thyroid gland, the patient felt perfectly well, the eye no longer protruded, the pulse was less frequent than formerly, and there was no discomfort or dyspnea.

Pseudo-tuberculosis.—At a meeting of the Société de Biologie, CHARRIN (*La Médecine Moderne*, No. 43, 1891, p. 745) reported a case of granular tuberculosis, in which, post mortem, lungs, spleen, and liver contained large numbers of gray granulations, in which tubercle-bacilli could not be found. Animals inoculated from the granulations died and presented similar lesions, in which were found bacilli that stained by ordinary methods.

THE EMPLOYMENT OF EPILEPTICS.

THERE is in this country no right provision made for many classes of people abundantly willing to labor for their own support, but who, by reason of partial and occasional disablement, are unfitted to compete in the open labor mart. These are the victims of many different maladies, but especially those suffering from one of the most unfortunate of human diseases, and one that is of the most ancient origin, namely, epilepsy, or the "falling sickness." The epileptic is not specially set apart from his fellows in childhood or early youth, or if in comfortable circumstances, but the moment he applies for work, and his malady becomes known, a sharp line is at once drawn. Be he ever so intelligent or industrious, this accident of disease constantly stands like a black mark against his name. His presence is only tolerated; he is got rid of at the earliest possible moment, and the difficulty of getting other work increases in geometric ratio, until presently he is relegated to the lumber-heap of incompetents, or becomes a hopeless pauper.

In a paper read before the Philadelphia Neurological Society last year on this subject, DR. J. MADISON TAYLOR, long deeply interested in this subject, says:

"If an employer be merciful and desires to give an epileptic a job, especially if this be among machinery, and if in a fit this poor creature falls and hurts himself, the law gives him the right to sue for damages, and, unjust as this may appear, it is often done. Even in the ranks of domestic labor a female servant cannot be tolerated long who falls ever so rarely in a loathsome-looking fit.

"Thus one way or another the door to honest labor is shut. Add to these constant disappointments the highly emotional nature so often a part of the disease before and after the fit, the inevitable mental and moral weakening that the disease breeds, and the sufferer may well be looked upon, as by the ancients, as a victim of the especial and fiercely directed anger of the gods.

"Could there be had a wisely devised series of havens for such, where the worst cases might be housed and others received daily, and all employed in proportion to their powers, it would constitute a worthy charity. Charity should be clearly distinguished from alms-giving. The great petition that goes up from humanity is for opportunity. Those that have good brains must choose and plan for those that are lacking. Such a system would offer immeasurable opportunities for the study, relief, and cure of the dread 'falling sickness.'"

DR. FREDERICK PETERSON has pointed out the consequences of this exclusion of the epileptic from the ordinary occupations of humanity:

"He is driven to find shelter in an asylum, not, as a rule, because he is deprived of reason, but because there is no other place for him to go. There are thousands of epileptics in insane asylums to day who do not belong there; for many will be found among them who are not insane, and it is an injustice to them as well as a detriment to the insane to associate the two classes. When we take into consideration the fact that a large majority of these unfortunates are gifted with as much intelligence as ordinary human beings, that they are as capable of education, as well adapted for everyday pursuits, quite as able to be self-supporting as most people, their unutterable woes become more apparent. But the conditions under which they may secure their proper mental development and their need of occupation must be such as combine medical supervision with wise industrial teaching and training. It was considerations of this kind that led Pastor von Bodelschwingh, twenty-four years ago, to establish a colony for epileptics at Bielefeld, near Hanover, in Germany. For nobility of conception and for excellence of result it is unique in our civilization. It seemed to this benevolent founder that it was feasible to create a refuge where, if curable, such sufferers might be cured; where at least their condition might be ameliorated, their intellectual decay prevented; where they might find a comfortable home if recovery were impossible; where they might develop their clouded mental faculties to the utmost, might acquire trades or engage in any occupation they saw fit to choose, and finally to grow into a community of educated, useful, industrious, prosperous, and contented citizens. There has been a fair realization of this project, and there has been a gradual evolution and expansion of the colony. Now it has over one thousand epileptic inhabitants.

When I visited it in 1887 it consisted of fifty-five houses and cottages, scattered in pretty gardens over some 320 acres of beautiful woodland and meadows. It was like a country village."

At this place are schools, stores, and shops of many kinds, a foundry, saddlery, dairy, brickyard, printing-office, and bookbindery—in fact, all of the factors that go to make up a well-rounded small community. These sufferers do all the work and do it well; they build houses, make bricks for the purpose, are excellent carpenters and good iron-workers, good painters and glaziers. For the men alone there are thirty different callings. The women are busied in the manifold cares of the households, manufacturers of wearing apparel and bed-linen, and the rearers of flowers and garden products. It would be useful to further describe this admirable little community, its work and its play. A full description is given by DR. PETERSON in the *Journal of Nervous and Mental Diseases*, December, 1889. Since this colony was started, nine other epileptic colonies have been established in Germany, one in Holland, and one in Switzerland. It is admitted that in the United States there are at least two epileptics to every thousand of population; hence, in the United States there must be over one hundred thousand persons suffering from this malady. The only difficulty in speaking of this matter is not to say too much, or to speak in a manner not to seem exaggeration. That systematic methods should be pursued in caring for epileptics needs no further demonstration. That which has been done in this country is as follows: A bill was introduced in the New York Senate by DR. PETERSON through SENATOR W. L. BROWN, and is now in the Committee on Public Health. We do not know what action has been taken in this matter recently, but even if the commission be appointed for selection of site and preparation of plans for a suitable institution, the realization of the ultimate result must inevitably be long deferred. There is one institution recently established at Gallipolis, Ohio, but we are not acquainted with its details and present work. In Boston DR. WILLIAM M. BULLARD read a paper last year before a section of the District Medical Society upon this subject, and a special committee of the Massachusetts Medical Society was appointed to consider it. There, so far as known, the matter now stands. This committee proposes to introduce a bill into the next Legislature, but in regard to the details of this bill nothing has yet been decided beyond the fact that at present the cottage-hospital system seems the most commendable.

But some action should be taken more broadly than would be possible in one city or State. If this idea, clearly defined, could be brought before the attention of any legislative body in America, it would certainly gain the most earnest support of all. Unfortunately, it would take an enormity of work and individual effort to secure this, and were it once secured the whole project might run dangers of being wrecked on partisan considerations.

If only the earnest workers in practical medicine throughout the United States—those conscientiously striving to limit the woes of their fellow-men—would give this reform their attention and active support, practical results would infallibly follow. It seems a subject eminently proper and worthy of being considered by medical associations, local and congressional.

AT WHAT AGE MAY A WOMAN MARRY?

THE question as to the suitable age for a woman to marry is one that concerns alike the philosopher, the political economist, the moralist, and the physician. It involves so many interests, and needs to be studied under such different aspects, that it is not strange the answers are sometimes widely different.

PLATO, in his *Republic*, asserted that twenty years was the proper age for a woman's marriage, while he deferred that of man until the age of twenty-five. MALTHUS regarded late marriage as the most important check to an increase in the population greater than the increase in means of subsistence. Wise political economists in general would postpone marriage until there is a reasonable assurance of ability to support a family. But the Catholic priest, looking at the question from a moral and religious point of view, holds that postponement of marriages among a large body of men is the fruitful source of evil. MR. LECKY, in his *History of European Morals*, makes the following statement: "The nearly universal custom of early marriages among the Irish peasantry has alone rendered possible that high standard of female chastity, that intense and jealous sensitiveness respecting female honor, for which, among many failings and some vices, the Irish poor have been preëminent in Europe; but these very marriages are the most conspicuous proofs of the national improvidence, and one of the most fatal obstacles to industrial prosperity."

The influence of idleness in hastening marriage is unfortunately quite positive. It would seem that manual laborers when out of work would postpone marriage, but observation proves that in many cases this is an error. For example, it has been observed at Manayunk, Philadelphia, that during strikes in manufacturing establishments marriages among the unemployed operatives are more frequent. The evil consequences of such untimely and improvident marriages are that pregnant women frequently do not have proper food, care, and rest, and that many a babe comes into the world without having been provided with suitable clothing to cover its nakedness and to protect it from one of the first perils of infant life—cold. If a law were made forbidding a woman to marry until the proposed husband could prove that he was able to support her and their children, the number of marriages would materially lessen; but, as in the old mythology, Cupid is blind, and law is impotent to govern those pierced by his arrows; certainly, however, wisdom will be justified of her children who do not rush into matrimony when the alliance inevitably leads to pinching poverty and squalid misery.

It is possibly true that early marriages may be advisable as a prophylactic against licentiousness; but it is protection of the male primarily rather than of the female that is thus sought. If young men had suitable and sufficient physiological, moral, and religious training, the necessity for such prophylaxis would be lessened. If, furthermore, the pitiless and inexorable judgments that society commonly visits upon the poor girl who lapses from virtue—branding her with a pariah-curse, and her offspring with a bastard's name and shame—were not thus restricted, if it were correspondingly severe to the author of her ruin, there would be less difficulty in deciding the matrimonial problem: a scheme of morals that punishes one transgressor exclusively fails in justice, and cannot abide—equal guilt demands equal punishment, without regard to sex. In certain circles the seducer is readily forgiven, and the man who has habitually associated with prostitutes can enter their sacred bounds, and in virtuous households become eligible and accepted as a husband, while the same households would not so much as let one of his former female associates be admitted into their kitchens, when she was endeavoring to end a life of shame and earn an honest living by daily toil. A woman had better never marry than open a private hospital and reformatory for a diseased and dissolute man. Too many young men are sowing wild oats, not thinking of the inevitable harvest—one that not only they, but also their wives and children must reap—of suffering, sorrow, disease, and death, instead of joy, happiness, health, and life. "Stop the licentiousness of men," said an experienced surgeon, "and more than one-half of the grave abdominal operations performed upon married women, so frequent in recent years, would not be needed."

But while the physician is political economist, moralist, and philosopher, or at least ought in some degree to be all these, looking at the question solely from a professional standpoint, the recently published investigations of KÖRÖSI at Budapest show that mothers permit their daughters to marry earlier than is best. According to his statistics the mortality of children is much greater when born from early marriages, while such of these children as do survive are not strong and healthy. In order that this mortality be reduced to the normal, the mother should be twenty-five years old when commencing to bear children. The young man of twenty is also too young to marry, if the interests of the children be considered. Furthermore, fecundity, *per se*, is not a cause of child-mortality if the parents have married at a suitable age, because, while true that this mortality is greater in large than in small families, the chief cause is found in the poverty of the former. Here again it seems that the question of marriage belongs in part to political economy. But in general it may be stated that a woman is wise who delays her marriage until she is twenty-four or twenty-five years of age; at least, this is the plain lesson to be learned from KÖRÖSI'S investigations.

THE TREATMENT OF VALVULAR LESIONS OF THE HEART.

A SHORT time ago we incidentally took occasion to state that the mere existence of a valvular lesion of the heart is of itself not an indication for treatment. It is rather the rational signs of deranged function that furnish the indication. The condition of health depends upon the perfect performance by every organ of its respective function, as manifested by the maintenance of the systemic equilibrium, a disturbance of which constitutes disease. To be successful the treatment of disease must be directed to a restoration of the equilibrium, and the first

step consists in the removal, when possible, of disturbing elements. If these be irremediable, the indication is by natural or artificial means to make good or to neutralize the existing deficiency. That which in disease is analogous to the condition of normal equilibrium is known as compensation—and the attainment and the maintenance of this must be the ultimate aim of any therapeusis. There are two modes by which this object may be accomplished: 1, by whipping up the failing organ, or 2, by reducing the demands upon it.

In a most interesting and philosophic paper on the treatment of valvular disease of the heart, Liebermeister (*Deutsche medicinische Wochenschrift*, No. 46, 1891) makes medicinal treatment subordinate to mechanical treatment. The former is to be employed when definite indications exist; the name by which the lesion is known does not furnish the indication; each case must be judged for itself. In not a few cases there is a spontaneous tendency to the establishment of compensation. The reserve or latent force of the heart, that which in health is not ordinarily called into activity, is in disease drawn upon—and this is a point that practitioner and patient should realize. A heart embarrassed by a valvular defect may be competent to meet ordinary demands, but it will fail in the face of extraordinary demands. The functional capability of the individual heart must in each case be determined and the burden to be placed upon it regulated accordingly. Compensation for valvular defects means hypertrophy, but this dare not be excessive, for overgrowth begets premature degeneration.

Graduated cardiac gymnastics is an important factor and a useful adjuvant in the development of a compensatory hypertrophy. When shortness of breath and palpitation of the heart are absent, it may be considered that compensation has been established. Once established, it is necessary to its maintenance that the general nutrition, and with it that of the heart, be maintained.

The mechanical means of treatment of disease of the heart may well and often necessarily must be supplemented by the judicious employment of drugs. The best agent, that most general of application and the most reliable, is digitalis; but it should not be forgotten that a condition of tolerance, of insusceptibility to digitalis is soon established. To obtain the best results, the drug should not be continuously administered for a period longer than three or four weeks, and its administration should not be resumed until an interval of four weeks has elapsed after its withdrawal. The longer the interval that can safely be allowed to elapse, the better the result, both immediate and remote. If the valvular defect is great, or if the muscular fiber of the heart be degenerate, digitalis may fail to effect compensation. In some cases in which digitalis fails, one of its congeners, such as strophanthus, convallaria or caffeine, may succeed. Strychnine or atropine may prove of service. Calomel in small doses acts admirably as a diuretic. Laxatives find a useful place in treatment. Diaphoresis may be serviceable, though care must be observed that the temperature of the patient be not raised above 102.5°. Paracentesis may be necessary to remove accumulations of fluid; multiple puncture to diminish the degree of anasarca. A dry diet may accomplish like results, but it cannot be rigidly enforced. Tepid baths or brief applications of cold to the precordia may be sedative to an overacting heart. Alcohol, ammonia, or camphor may be required as stimulants. Under certain conditions of embarrassed circulation, when other measures have failed, brilliant, though perhaps only temporary, results may be obtained by free venesection. Venesection is indicated when manifestations of otherwise irremediable blood-stasis exist, as indicated by symptoms of pulmonary and of cerebral edema. We believe that when degeneration of the myocardium coëxists with valvular lesions, good may be accomplished by the employment of nitro-glycerin. The injunction to treat the patient and not the disease applies with especial emphasis to cases of valvular lesion of the heart.

SELECTIONS.

THE INFLUENCE OF INFLUENZA ON THE ENGLISH DEATH-RATE OF 1890.

The report of the Registrar-General for 1890, relating to the births, marriages, and deaths in England and Wales during that year, has just been issued. The birth-rate, which had shown a continuous decline since 1876, was the lowest recorded during any of the last fifty years, although the marriage-rate during the last four years has shown a steady increase, and was higher in 1890 than in any year since 1883. With regard to the deaths during the period under review, it appears that the standard of public health reached in recent years was not maintained during 1890. The death-rate, which had been 19.1, 18.1, and 18.2 per 1000 persons living in the preceding three years, 1887–88–89, rose to 19.5 during 1890. It should be noted, however, that

compared with other earlier years, this death-rate was still a low one; for in none of the ten years, 1881–90, was the death-rate as high as 20.0 per 1000, whereas in no year previously to 1881 was it ever so low. The increase in the rate of mortality in 1890 is attributable to the epidemic of influenza, to which, although it was generally prevalent only during the first quarter of the year, 4523 deaths were directly ascribed. This, however, probably represents but a small proportion of the mortality really attributable to influenza; for the immense increase in the mortality from respiratory diseases at the same time, notwithstanding the mildness of the season, was clearly due to the same cause. The Registrar-General estimates the number of deaths directly or indirectly due to epidemic influenza in 1890 at upward of 27,000, which is equivalent to a death-rate of almost one per 1000. It is satisfactory to note that the mortality from nearly all other zymotic diseases was below the average. Only 16 deaths resulted from small-pox in 1890, the smallest number in any year on record. The deaths referred to constitutional diseases, especially to phthisis, showed a marked increase, probably attributable to the fact that a number of persons of phthisical constitution were prematurely carried off by the influenza epidemic during the earlier part of the year.—*Brit. Med. Journ.*

THE INFLUENZA-BACILLUS.[1]

I. Preliminary Communication on the Exciting Causes of Influenza. By DR. R. PFEIFFER, Chief of the Scientific Section.

The following results are based on the accurate examination of thirty-one cases of influenza, in six of which a necropsy was made. A complete report will be published as soon as possible:

1. In all the cases of influenza a bacillus of a definite species was found in the characteristic purulent bronchial secretion. In uncomplicated cases of influenza these tiny bacilli were found in absolutely pure cultures, and mostly in immense quantities. They were very frequently situated in the protoplasm of the pus-corpuscles. If the influenza had attacked persons whose bronchial tubes were already otherwise diseased—as, for example, tuberculous patients with cavities—other microörganisms besides the influenza-bacilli were found in the expectoration in variable quantity. The bacilli may penetrate from the bronchial tubes into the peribronchial tissue, and even reach the surface of the pleura, where, in two cases examined *post mortem*, they were found in pure cultures in the purulent exudation.

2. These bacilli were found exclusively in cases of influenza. Very numerous control examinations proved their absence in ordinary bronchial catarrh, pneumonia, and pulmonary tuberculosis.

3. The presence of bacilli kept equal pace with the course of the disease; with the cessation of the purulent bronchial secretion the bacilli began to disappear.

4. I had already seen and photographed similar bacilli in the same enormous quantities two years ago, during the first epidemic of influenza, in preparations of the sputum of patients suffering from the disease.

5. The influenza-bacilli appear as very tiny rodlets, of about the thickness of the bacilli of mouse-septicemia; but only half the length of these. One often sees three or four bacilli strung together in the form of a chain. They stain with some difficulty with the basic anilin dyes. Better preparations are obtained with dilute Ziehl's solution and with hot Löffler's methylene-blue. In this way it can be seen almost as a rule, that the two ends of the bacilli take the stain more intensely, so that forms are produced that can only with great difficulty be distinguished from diplococci or streptococci. In fact, I am inclined to believe that some of the earlier observers also saw the bacilli described by me, but that, misled by their peculiar behavior with regard to staining agents, they described them as diplococci or streptococci. The bacilli cannot be stained by Gram's method. In hanging drops they are immobile.

6. These bacilli can be obtained in pure cultures. On 1½ per cent. sugar-agar the colonies appear as extremely small droplets, clear as water, often only recognizable with a lens. Their continued culture on this nutrient medium is attended with difficulties, and up to the present I have not succeeded in carrying it beyond the second generation.

7. Numerous inoculation-experiments were made on apes, rabbits, guinea-pigs, rats, pigeons, and mice. Only in apes and rabbits could positive results be obtained. The other species of animals showed themselves refractory to influenza.

8. In view of these results, I consider myself justified in pronouncing the bacilli just described to be the exciting cause of influenza.

9. It is very probable that infection is produced by sputum charged with the germs of the disease; and the disinfection of the sputa of patients suffering from influenza is therefore urgently required as a prophylactic measure.

Addendum.—Dr. Kitasato has succeeded in cultivating the influenza-bacilli to the fifth generation on glycerin-agar.

II. On the Influenza-bacillus and the Mode of Cultivating it. By DR. S. KITASATO.

It is, perhaps, remarkable that in the case of a disease that in the last few years has attacked hundreds of thousands of persons, the specific exciting causes have, in spite of extremely numerous investigations, only lately been discovered. The cause, in my opinion, lies in the extreme difficulty of cultivating the tiny bacillus, and, without pure cultures a bacteriologist cannot, of course, come before the public with a new specific microörganism.

The difficulty of obtaining cultures of specific bacteria present in the sputum depends chiefly on the great contamination with microörganisms from the mouth, etc. The latter, in consequence of their more luxuriant and abundant growth, can, on our artificial nutrient media, completely overgrow and hide the particular parasites sought for. This occurs all the more easily the longer the time required for the specific parasitic microörganism in question to form colonies, as in fact happened in the case of the tubercle-bacillus.

[1] From the advance proof-sheets of the *Deutsche medicinische Wochenschrift*, in the *British Medical Journal* of January 16, 1892.

With the view of avoiding the obstacles in the way of a successful cultivation, Privy Councillor Koch has devised a method that has not yet been published, which enabled him many years ago, and myself again quite recently, to obtain pure cultures of tubercle-bacilli directly from the sputum, and which has also now been followed by me. The method to which I have just referred will soon be published in full detail.

With regard to the characteristics of the pure cultures of influenza-bacilli, I may emphasize the following points: On a sloping surface of set glycerin-agar the individual colonies present themselves as extremely small points, like droplets of water, recognizable during the first twenty-four hours only with the aid of a lens, so that macroscopically a test-tube containing them can scarcely be distinguished from a sterile one. The individual colonies are, as has been said, so unusually small that they may easily be overlooked, and it may thus have happened that previous investigators have overlooked them.

If a culture obtained from such a colony is placed on a new nutrient agar medium, numerous small colonies arise on the moist agar surface. A particularly remarkable point is that the colonies always remain separate from each other, and do not, as colonies of all other species of bacteria known to me do, join together and form a continuous row. This feature is so characteristic that the influenza-bacilli can thereby with certainty be distinguished from other bacteria.

The possibility of continued cultivation is now demonstrated. I have been able to reach the tenth generation in pure cultures. On gelatin the bacilli do not grow, as they do not generally multiply at a temperature lower than 28° C., which is the temperature at which gelatin solidifies. In bouillon they grow scantily. In the first twenty-four hours, single white particles are seen swimming in the bouillon, the intervening fluid being perfectly clear. Later, they sink to the bottom, and there form a white, woolly mass, whilst the supernatant bouillon remains entirely clear—a proof that we have to deal with an immobile bacillus. In conclusion, I may remark that I have accurately studied with the microscope and by culture for a long time the sputa of tuberculosis in respect to all the microörganisms besides the tubercle-bacillus occurring therein, and also the sputa of pneumonia, bronchitis, etc.; but the present bacillus, so extraordinarily characteristic in its cultures, and so easily to be recognized, has not come within my experience except in influenza patients.

III. On a Microörganism in the Blood of Influenza Patients. By Dr. P. Canon, Assistant Physician in the Hospital Moabit, Berlin.

During the last few weeks I have, under the direction of Dr. P. Guttmann, examined the blood of twenty influenza patients in stained preparations, and in almost all cases I have found in the blood one and the same microorganism. The examination of the blood was made in the following way: A drop of blood obtained by pricking the finger was received on a perfectly clean cover-glass; this cover-glass was placed upon another, and the two then drawn apart. The preparations, after they had been thoroughly dried, were placed in absolute alcohol, in which they were left for at least five minutes. They were then taken out and placed in the following staining solution (Czenzynke's solution): ℞.—Concentrated watery solution of methylene-blue, 49 grams; ½ per cent. eosin solution (dissolved in 70 per cent. alcohol), 20 grams; distilled water, 40 grams. The cover-glasses immersed in this staining solution were placed in an incubator at a temperature of 37° C., and left there for from three to six hours, when they were washed with water, dried, and imbedded in Canada balsam. In the preparations of blood made in this manner, where the red blood-corpuscles were red and the white ones blue, I found the microörganism referred to. It is found stained blue, sometimes in large quantities, but mostly sparingly, and only to be identified after a long search (about 4 to 20 in the preparation). Sometimes it appears as a small diplococcus; sometimes, especially when it is more deeply stained, as a short bacillus.

In six cases I have found it also in numerous larger and smaller heaps of from five to fifty individual microbes with a very characteristic appearance. In these six cases, the blood was drawn during a fall of temperature or shortly afterward; in three of these, no further rise of temperature occurred. From three to six days later I failed to find the microörganism in the blood in these three last cases. Sometimes by means of preparations of the blood alone, I have been able to make the diagnosis of influenza, when clinically it was not certain. I have also found the bacteria in the blood, and, indeed, in considerable quantities in cases in which there was no appreciable local lesion, and especially no cough or expectoration. While making the preparations I have generally at the same time made streak-inoculations of the blood on agar-glycerin-agar, sugar-agar, and bouillon. In six cases the bouillon was injected into mice, partly at once, partly on the following day after it had been in the incubator. These inoculations and experiments on animals always yielded a negative result. As on the basis of my researches I am of opinion that this microörganism occurs in the blood of all persons suffering from influenza (at least, in that of those who have fever), and as it is not found in the blood of other persons, and as it is a microörganism hitherto unknown, I believe that it stands in direct relation to influenza.

Privy Councillor Koch had the goodness to examine some of my preparations, and pointed out that the microörganism visible in them was identical with the bacterium found by Staff-surgeon Dr. Pfeiffer, which has been described in the preceding paper, which is published at the same time as mine. I began these researches about the middle of December; I have, however, still a large number of preparations to stain and to examine. I propose to publish the results of the further research in a later communication.

CORRESPONDENCE.

ON THE INFLUENZA EPIDEMIC OF 1789.

To the Editor of The Medical News,

Sir: It may be of interest to some to recall a few facts from an article in the *American Museum*, better known

as the *Universal Magazine*, on the epidemic of influenza that raged in this country during the Fall of the year 1789.

The epidemic began in the latter part of September, lasted six weeks, and spread very rapidly, disappearing as fast as it came, leaving quite a number in a very weak condition. The weather during the summer had been very dry; no rain falling, all ponds had been dried up, and were emitting foul odors; the thermometer was continually above 90°. The mortality is not given, but it is mentioned that when lung-trouble or consumption existed a speedy death was probable. Hard drinkers and old people were the first to die. To people at the seashore it was almost always fatal,[1] while people living an out-of-door life, such as sailors, longshoremen, etc., would have a much more severe attack than would men working indoors.

Two prominent symptoms were a feeling of fulness and stricture about the precordia, and an acrid discharge from the nose and bronchi that excoriated the mucous membrane, leaving about the nose and mouth large granulating sores for some time after.

Acute pain was felt in the head, fixed between the eyeballs, while Rush (page 355) reports "three cases which terminated in abscesses of the frontal sinus which discharged themselves through the nose. The pain before opening was so intense, the person almost losing his reason." Many complained of great itching in the eyelids; in some the lids were swollen, while others had true ophthalmia.

The ears were often involved, mastoid tenderness being very frequent, showing the implication of the mucous membrane of the Eustachian tube. Taste was often lost; toothache and swelled jaws were frequent.

On from the fourth to the fifth day the case would end by a free diaphoresis (Rush says "the sweats were very profuse, but afforded no relief to the patient"), leaving the person very weak, with a tedious cough, which, if the patient were susceptible, ran into pulmonary tuberculosis—in two cases into asthma.

The treatment seemed to have been rather varied, but that found best was the giving of mucilaginous drinks and fresh air in the room; small doses of antimonials and mild saline laxatives. Bleeding and opium, when used for the pain and fulness, were found to do more harm than good, and so were not much used.

During convalescence, bitter tonics and mucilaginous drinks soon placed the person in a condition to attend to his work.

In another part of the book the following was found, which was called *an effectual cure*: "Take four or five eggs and cover them with vinegar or lime-juice and allow to remain till the shells be dissolved, then add to them the following: Honey, brandy, sweet oil, āā Oss. S.: Take one tablespoonful every three or four hours."

In the spring of 1790 the influenza reappeared; everybody was again taken down with it, but those that suffered from affections of the head in the Fall were now afflicted with an attack that fell on the lungs and back, and *vice versa*.

Respectfully yours,

EDWIN S. POTTER, M.D.

1913 SPRUCE STREET, PHILADELPHIA.

HEMORRHAGE IN TYPHOID FEVER.

To the Editor of THE MEDICAL NEWS,

SIR: The experience of Dr. Rodman (THE MEDICAL NEWS, January 9th) according so exactly with my own, I wish to give a treatment adopted by me some two years since for hemorrhage complicating typhoid fever. I have passed through two rather severe epidemics, and since, during this time, I have had perfect recovery in every case, the treatment certainly deserves consideration. It is very much like the zinc carbolate treatment of recent years, yet I had never heard of this zinc carbolate when I began using my formula. Under its use I have not had a single hemorrhage that demanded or received special notice or medication. I do not recall a case in which the tongue became brown or dry (a condition common under the old *régime*), when so treated from the beginning. I have taken charge of cases on about the twelfth day, the patient having a dry, brown tongue, pointed, and intensely red around the edges, and have had this condition to disappear like magic.

I have learned long since, that all things must be thoroughly tested before we can rely on them; that, although my cases have all recovered, it might not be due to a special line of medication, but to the fact that I have been fortunate in securing remarkably light cases, my fellow-practitioners losing theirs because they happened to get severer, or more complicated cases. Yet it seems that during more than two years of experience with this treatment, covering many cases, of all ages, I surely would have had all types to contend with.

Leaving a discussion of all symptoms out of the question, just as soon as I find I have typhoid fever to contend with I place adults on a sulpho-carbolate of quinine treatment, giving them—

℞.—Quininæ sulph. }
Potassii chlorat. } . . . āā gr. x.
Acid. carbol., pur. . . . ♏ x.

Capsules, no. x.

S.—One every four hours, with two, three, or four drops of oil of turpentine.

I know the quinine sulph. and acid carbol. are antidotal to each other, and that the resultant compound is insoluble, yet this very fact made it the more rational, because I did not care whether the remedy was dissolved in the stomach, or waited until it reached the lower bowel before assimilation. It does not matter whether the treatment is rational or not; it has proved a powerful factor for good in my hands, whether or not this is due to its beneficial effect or to its insolubility, and consequently the doing of nothing according to the expectant plan. Instead of the new and depressing antipyretics, I use tincture of veratrum viride, in doses of one, two, or three drops as necessary, to control fever. I feed persistently from the beginning with fluid foods, using both beef and bird soups, and sweet and butter-milk, alternating these and insisting on one of them at least every two hours. Of course, complications are met as they arise, but in the main the treatment is persistently adhered to from beginning to ending of the fever. I firmly

believe that it will shorten the duration of every case of fever by several days.

Very respectfully,

J. E. STINSON, M.D.

MONTAGUE, TEXAS.

IVORY PEGS.

To the Editor of THE MEDICAL NEWS,

SIR: In an article by Dr. O. H. Allis, on "Ununited Fractures" (THE MEDICAL NEWS, January 2, page 3), the author says that pegs are not absorbed; that suppuration takes place, and that fixation is not satisfactory.

There are certainly exceptions to this rule. I have only used ivory pegs once—in an ununited fracture of the tibia: one peg was almost wholly, and the other one-fourth absorbed at the end of five weeks. There was no suppuration, and fixation was satisfactory. If desired I will send what remains of the pegs.

Respectfully yours,

G. S. ARMSTRONG, M.D.

OLYMPIA, WASH.

NEWS ITEMS.

The Annals of Ophthalmology and Otology is a new quarterly of 74 pages of excellent reading matter, well printed, and edited by Dr. J. P. Parker, of Kansas City, Mo. The subjects united in the title seem to imply that the two specialties are often still conjoined by the single practitioner.

The Medical Fortnightly is the name of a new journal to be published at St. Louis on the first and fifteenth of each month. The first number bears the date of January 1, 1892; it presents a neat appearance, and contains several interesting articles. Dr. Bransford Lewis is the editor-in-chief; he will be assisted by a number of associates.

Seventh Annual Report of the Adirondack Cottage Sanitarium.—For the year ending November 1, 1891, one hundred and thirty-six tuberculous patients were treated at the Adirondack Cottage Sanitarium. There were but two deaths, and these in advanced cases. Of seventy-seven patients discharged, fourteen were apparently cured; in twenty-three the disease was arrested; twenty-two were improved and eighteen were unimproved. The results were better in proportion to the time that patients remained under treatment. In eighteen cases injections of tuberculin were conjoined with the usual treatment. Of the six of these cases discharged, two were apparently cured; in two the disease was arrested; one was improved, and one was unimproved.

Leprosy in Russia.—The first leper-house in the Baltic provinces of Russia was recently opened at Riga. It is intended, provisionally, to accommodate twenty men and seventy women. The medical and administrative staff live in a separate building, and the attendants live as remote from the patients as possible.

A Balneologic Congress will be held at Berlin from March 10th to 13th, under the presidency of Professor Oscar Liebreich.

ACUTE EDEMA OF THE LARYNX, WITH THE REPORT OF A CASE RESULTING FROM PYEMIA.[1]

BY J. H. BRYAN, M.D.,
OF WASHINGTON, D. C.,
LATE PASSED ASSISTANT SURGEON U. S. NAVY; LECTURER ON DISEASES OF THE NOSE AND THROAT IN THE MEDICAL DEPARTMENT OF THE COLUMBIAN UNIVERSITY; SURGEON TO THE THROAT DEPARTMENT, GARFIELD MEMORIAL HOSPITAL.

THE importance and rarity of acute edema of the larynx justifies me in calling attention to an interesting case of this affection that recently occurred in my practice:

On February 2, 1891, I was called in consultation with Dr. C. V. Boarman, of Washington, to see the patient, G. S., aged thirty years, a fish-dealer by occupation, and a man of strong physique. Upon entering his room I found him breathing rapidly and with great difficulty, but there was no audible stridor. The man's face was flushed and presented an anxious expression; the voice was husky, with a peculiar metallic quality; deglutition was painful and difficult. There was some swelling of the neck, and over the left thyroid gland there was an enlargement, about the size of a pigeon's egg, which was very painful on pressure. He expectorated a thick purulent secretion, the expulsion of which was attended by sharp, lancinating pain.

On examination of the throat, there was observed a slight redness of the posterior wall of the pharynx and of the fauces; but the parts could not be said to be the seat of active inflammation. By means of the laryngeal mirror, I found the epiglottis to be enormously swollen and very red, projecting from the base of the tongue over the laryngeal cavity, so that the interior of this could not be seen. Lying on either side of the swollen epiglottis, between it and the lateral walls of the pharynx, was thick, purulent secretion.

As the necessity for relief of the impending suffocation was so urgent, without further questioning the patient, I freely scarified the epiglottis with the laryngeal lancet. Each incision was followed by a discharge of blood and pus, and to encourage the discharge the patient was directed to gargle with warm water. In a short while, he expressed himself as feeling very much relieved, although I was unable to detect any diminution in the swelling of the epiglottis. Ice was applied externally, and the man was directed to swallow cracked ice frequently. In less than two hours the patient was again seen, and found in a state of great excitement, as he felt worse, and the dyspnea seemed to be increasing.

Examination showed the epiglottis still to be greatly swollen. I scarified again, making deeper incisions than before. The flow of blood was not very profuse, but the patient was able to expectorate more freely, the expectoration still being thick and purulent. This gave him more relief than he experienced from the first scarification, and the swelling was perceptibly lessened. Ice internally and externally was continued during the night. On the following morning, the patient was somewhat improved as to breathing and deglutition, but the voice was about the same. The epiglottis was found to be still very much swollen—so much so that the interior of the larynx could still not be seen. Scarification with deep incisions was again practised.

At the Garfield Hospital, whither the patient was now sent, the following history was obtained:

He had had frequent attacks of sore-throat, but they were always mild in character, lasting only a few days. For the past three years he had led a very intemperate life, and on one occasion was confined in an inebriate-asylum. He had never had syphilis, but several years previously he had a small venereal ulcer on the prepuce, which healed in a few days; no constitutional symptoms have ever developed. On the 9th of November, he contracted gonorrhea, for which he was treated by internal medication; but the discharge, while becoming less, never entirely ceased. On January 9th, he consulted a prominent surgeon, who, in addition to prescribing internal medication, passed a sound for the relief of a deep-seated stricture. The sound was passed for the second time, January 26th, and that night he had a severe chill; feeling ill on the following day, he took a Turkish bath, but without experiencing any relief. He continued to feel somewhat ill, with occasional chilly sensations, until February 1st, when he experienced a severe pain in the larynx, attended with great difficulty in breathing. About the same time he noticed that his neck was swollen. These symptoms increased in intensity until I saw him on the following day, and found the condition that I have already described.

February 3—the day of admission to the hospital: His temperature was 103°; pulse, 106; respirations, 30. There was a slight purulent discharge from the urethra. Examination of the urine revealed nothing abnormal, save a large number of pus-cells. I continued ice internally and externally; gave $\frac{1}{12}$ grain of muriate of pilocarpine hypodermatically, and kept water impregnated with the compound tincture of benzoin boiling in the room.

[1] Candidate's thesis presented to and accepted by the Council for membership in the American Laryngological Association at its Thirteenth Annual Congress, September 13, 1891.

4th, 8 A.M. The temperature was 99⅘°; pulse, 96; respirations, 30. Noon, temperature, 103⅘°; pulse, 108; respirations, 36. At 8 P.M., temperature, 103⅕°; pulse, 112; respirations, 42.

The patient was restless and did not sleep during the night; breathing was easier; the voice was not so hoarse; he was still expectorating a purulent secretion; the swelling of the neck was subsiding. Examination with the mirror showed a marked subsidence of the swelling of the epiglottis. In the evening the man complained of severe pain in the epigastric region and at the lower border of the left lung. The treatment of the previous day was continued, and in addition 3 grains of salol were given every three hours.

5th, 8 A.M. Temperature, 103⅕°; pulse, 108; respirations, 48. Noon, temperature, 103⅘°; pulse, 102; respirations, 44. At 8 P.M., the temperature was 102⅖°; pulse, 112; respirations, 48.

The pain at the lower border of the left lung continues. Examination reveals a diminution of the respiratory murmur over the lower part of the left lung, both anteriorly and posteriorly. No râles and no dulness on percussion are detected; the patient complains of pain and numbness in the left arm. The swelling of the neck has entirely disappeared; the swelling of the epiglottis has subsided, and for the first time the arytenoid cartilages and the ary-epiglottic folds are visible. The whole larynx is intensely red, the congestion extending as far down the trachea as can be seen. There is no indication of an abscess at the base of the tongue; the expectoration has ceased, and there is no pain on pressure over the larynx. The salol and ice were discontinued, and 3 grains of quinine were given every three hours; and the larynx was sprayed with a solution of tannin (gr. xx ad ℥j) at similar intervals.

6th, 8 A.M. Temperature, 101⅖°; pulse, 118; respirations, 44. Noon, temperature, 102⅖°; pulse, 116; respirations, 52. 8 P.M., temperature, 101⅘°; pulse, 114; respirations, 52. A pronounced jaundice appeared this morning. The treatment of yesterday was continued, with the addition of tr. ferri chloridi, gtt. xx, every three hours.

7th, 8 A.M. Temperature, 100⅘°; pulse, 120; respirations, 50. Noon, temperature, 102⅕°; pulse, 120, respirations, 40. 8 P.M., temperature, 100⅘°; pulse, 122; respirations, 46. Jaundice still continues; the patient complains of pain in the left hypogastric region. Percussion shows no increase in the area of hepatic dulness, and there is no sensitiveness on pressure.

8th, 8 A.M. Temperature, 100⅘°; pulse, 120; respirations, 50. Noon, temperature, 102½; pulse, 120; respirations, 50. 8 P.M., temperature, 100⅗°; pulse, 124; respirations, 50. The patient is very restless and weak; jaundice is not so marked; there is incessant cough, but no expectoration. Examination of the larynx shows no subsidence of the congestion, and there is little or no secretion in the larynx and trachea. About 9 o'clock on this evening, the patient complained of intense pain in the left hypogastric region, and suddenly cried out that "something had given way internally." I saw him at about 9.30, and found the abdomen somewhat distended and painful; the skin bathed in cold perspiration; the pulse feeble and scarcely to be counted. He did not rally from this condition, and died at 1.30 A.M., death resulting probably from the rupture of an abscess of the liver.

It was unfortunate that a post-mortem examination could not be obtained, so that the diagnosis could be verified.

It is possible that the disease commenced as a primary erysipelas of the larynx, to which the pyemia was secondary. I think, however, that the history of the case points more forcibly to the urethra being the source of the infection that caused the blood-poisoning, with a secondary phlegmonous laryngitis.

The history of acute edema of the larynx dates from 1765, when Morgagni[1] found, upon post-mortem examination, a serous infiltration of the mucous membrane of the soft palate, fauces, and larynx. It was not, however, until 1808, when Bayle[2] read his remarkable essay before the School of Medicine of Paris, that this disease received a place in pathology. He unfortunately gave it the name of edema of the glottis, which term we frequently find applied to cases of edema of the larynx even at this late period. After Bayle came Tuilier,[3] who in his thesis describes the symptoms of edematous laryngitis, and states that the fluid is either serous or sero-purulent. He was the first to establish by means of a digital examination the existence of cushions or pads caused by the swelling of the ary-epiglottic folds.

Finaz de Seisel,[4] was the first to suggest the passage of an elastic catheter into the larynx for the prevention of suffocation from edema of the larynx. It does not appear, however, that he ever performed this operation himself, but he had often seen it practised by Desault. Numerous memoirs appeared after those of Bayle and Tuilier, but it was Bouillard[5] that recognized the inflammatory nature of the disease. He reported three cases, in each of which the edema was of the secondary variety. Cruveilhier[6] also recognized the inflammatory nature of the affection, and gave it the name of submucous laryngitis. He divided the disease into supra-glottic and infra-glottic edema. In 1852, Sestier[7] wrote his elaborate treatise on edema of the larynx, and collected the surprising number of 245 cases. From these he compiled his statistical results, which have been made use of in every important communication on

[7] Traité de l'Angine Laryngée Œdemateuse. Paris, 1852.

the subject since that time. In 1862, Mandl[1] studied chronic edema of the larynx with the aid of the laryngoscope, and recognized the ary-epiglottic folds transformed into glistening cushions. This was the first communication on the subject after the introduction of the laryngoscope.

Acute edema of the larynx may arise quite independently of any inflammation; in such case it is characterized by an infiltration of a serous fluid in the submucous connective tissue of the larynx. It may occur in the course of hepatic obstruction, in acute and chronic nephritis, from malarial cachexia, from blood-stasis in the course of chronic disease of the heart and lungs, and, according to Von Ziemssen,[2] as a result of circumscribed obstruction in the laryngeal veins as a result of compression of the superior and inferior thyroid veins. That form due to inflammation is characterized by an infiltration of a serous, sero-purulent, purulent, and sometimes by a sero-sanguineous fluid in the submucous connective tissue. According to the statistics of Sestier, the disease seldom occurs before the age of fifteen years, and generally attacks persons between eighteen and fifty years of age, the majority of his cases being between eighteen and thirty-five years. Of 187 adults, 131 were men and 56 were women. Before thirty years of age the disease was generally a complication or sequel of some acute disease, while after that period it occurred in the course of chronic affections of the larynx.

In 1873, George von Hoffmann[3] found among 6062 post-mortem examinations made at the Berlin Charité, from 1869 to 1871, 33 cases of edema of the larynx, 10 of which were primary and 23 secondary. In 1879, Felix Peltesohn[4] found, in 3387 post-mortem examinations made at the same institution (from 1873 to 1878) 210 cases of acute edema of the larynx. Of these 149 were in men, 40 in women, and 21 in children. He found that the disease affected men generally between eighteen and sixty years, while the women were generally between eighteen and thirty-four years. Forty-four of his cases were due to local affections, and 164 were in consequence of general diseases.

In studying the etiology and prognosis of edema of the larynx, the statistics of Sestier cannot be taken as a guide, for it must be remembered that they were compiled before the days of the laryngoscope, when it was impossible to make a positive diagnosis. Furthermore, he did not separate the acute from the chronic form of the disease, and he included cases in which a dense deposit was present.

[3] Edema Glottidis, Berlin, 31. März, 1873.

[4] Berl. klin. Wochenschr., October 28, 1889.

The statistics of Hoffmann and Peltesohn, having been taken from the post-mortem room, represent only the fatal side of the question; and, as the latter author states, if the records of a large clinic were available, other figures than he gives would be obtained. It would also be interesting to know what influence the modern treatment of this affection has had on the rate of its mortality. For this purpose I have collected the cases on record in the library of the Surgeon-General's Office of the United States Army, and have found reports of 96 cases. Of this number 86 were in adults—73 in men and 13 in women, 2 being in negroes—and 10 in children. The majority of the cases were between twenty and fifty years of age. In the cases of children, 7 were under six years, the youngest being only five months. In 4 cases the edema was the cause of sudden death.

Edema of the larynx is said to be primary or secondary, but on this point authorities are not in accord. Gottstein[1] doubts whether it ever occurs as a primary affection, and believes that in the majority of cases it is partly or entirely due to local disturbances. Mackenzie[2] believes that in the cases of edema following simple inflammation, the disease is due to blood-poisoning. He states that in every case that has come under his observation ample opportunity of acquiring septicemia has been present. Virchow[3] is of the opinion that in all cases of acute edema without a clear etiology, the affection is really one of primary erysipelas of the larynx. Cases do occur, however, that are apparently primary, and in nearly all of them there is a history of exposure to cold, while the body is in a low state of health or after great bodily fatigue. By reference to the tabulated list of diseases causing edema of the larynx, it will be observed that bodily fatigue and exposure to cold constituted the cause in thirteen cases. Marboux[4] reports an interesting case, apparently of primary edema of the larynx, in a man, who prior to the attack was in perfect health. While bathing with some companions, his head was forcibly submerged under the water, and in less than twenty-four hours he had a severe attack of edema of the larynx.

The disease occasionally occurs in the course of an acute laryngitis; but it is more frequently due to the extension of an inflammation of the adjacent parts. I find that it was the result of an acute pharyngitis in three cases, of tonsillitis in six cases, in three of which the inflammation had progressed to

[4] "Reflexion sur l'étiologie et la symptomatologie de l'Œdema de la Glotte," Rec. du Mém. de Méd., Paris, 1875, 3 sér., xxxi, 382.

suppuration, and in one case it was due to an abscess in the tonsillar region.

Edema of the larynx is sometimes developed in the course of syphilitic and tuberculous inflammations of the larynx, although Gougenheim[1] thinks that true edema occurs very rarely in tuberculosis of the larynx, and, when it does occur, it is generally the result of caries of the cartilages. On the other hand, pseudo-edema is of much more frequent occurrence in the course of tuberculosis. This condition is not characterized by a collection of fluid in the cellular tissues, but by an infiltration of tuberculous material.

Diseases of the kidneys have long been recognized as constituting a cause of acute edema of the larynx, but an infrequent one. Fauvel,[2] in 1863, was the first to call attention to acute edema of the larynx as the primary symptom of disease of the kidneys. He reported three cases in which the edema was the first and only symptom of renal disease. Since that time Waldenburg[3] and De Bary[4] have made similar observations, the latter author reporting a case of acute edema of the larynx in a child as the first symptom of acute nephritis following scarlet fever. Among the general diseases that seem to give rise to edema of the larynx may be mentioned typhoid and typhus fevers, debility following chronic malarial poisoning, rheumatism, septicemia, and pyemia.

The following is a tabulated list of the cases that I have collected, showing the diseases that preceded acute edema of the larynx:

LOCAL DISEASES OF THE THROAT AND LARYNX.		GENERAL DISEASES.	
Acute laryngitis	9	Chronic disease of the kidneys	3
Subacute laryngitis	1	Typhoid fever	3
Pharyngitis	4	Typhus fever	6
Erysipelas	3	Debility following malarial fever	5
Tonsillitis	6	Rheumatism	1
Abscess in tonsillar region	1	Frost-bite and resulting gangrene	1
Tuberculosis of the larynx	3	Gastric fever	1
Diphtheria	1	Septicemia	1
Syphilis of the larynx	2	Pyemia	1
Extension of an inflammation of the cellular tissues of the neck	1	Part of a general edema for which no cause could be assigned	1
Straining of the vocal cords	2	Alcoholism	2
Scald throat	3	Variola	1
Consecutive to chronic bronchitis	1	Consequent on great bodily fatigue and exposure to cold	13
Ecthyma of the face extending into the larynx	1		
	38		39
Traumatism	5		
Following the administration of large doses of iodide of potassium	1		
On forcible submersion of the head under water	1		
	7		

Leaving the etiology in 12 cases unaccounted for.

In general, the edematous infiltration is developed in those parts of the larynx in which the submucous cellular tissue is in greatest abundance. These parts are the anterior surface of the epiglottis, the ary-epiglottic folds, and the ventricular bands.

Hajek[1] has recently made some interesting experiments on animals to discover the parts most prone to edematous infiltration. He finds that there is a layer of loose cellular tissue on the anterior surface of the epiglottis that passes up to within half a centimeter of its border and there ceases. From this point the membrane is firmly adherent to the cartilage. This cellular tissue on the anterior surface of the epiglottis is continuons with that lining the lateral walls of the pharynx in front of the pharyngo-epiglottic ligament. The ary-epiglottic folds are made up of two layers of cellular tissue, the internal being continuous with that found at the apex of the epiglottis on its laryngeal surface, while the external is continuous with that lining the pyriform sinus and the lateral wall of the pharynx behind the pharyngo-epiglottic ligament. This arrangement of the submucous cellular tissue and the position of the pharyngo-epiglottic ligament, which divides this part of the larynx into anterior and posterior portions, have a very important influence on the course of an edema. It is frequently observed that in edema of the ary-epiglottic folds due to local causes, such as ulcers, traumatism, perichondritis of the arytenoids, the infiltration is limited by the pharyngo-epiglottic ligament; and it is only when the edema is of great intensity and the collateral inflammation is decided in degree that this ligament is broken through. As the submucous cellular tissue of the anterior surface of the epiglottis and that of the ary-epiglottic folds are separated by the pharyngo-epiglottic ligament and pass up into the lateral wall of the pharynx on either side of it, it is clear that inflammations of the pharynx may occasionally extend to the anterior surface of the epiglottis, and occasionally to the ary-epiglottic folds, accordingly as the inflammation is on a plane anterior or posterior to the pharyngo-epiglottic ligament. Edema of the anterior surface of the epiglottis never passes over the border of this cartilage to enter the laryngeal cavity, and it only passes over into the ary-epiglottic folds when the infiltration is so extensive as to break through the ligament.

[1] "Anatomische Untersuchungen über das Larynx-œdem," Archiv für klinische Chirurgie, xlii, 146.

The edema is generally confined to that part of the larynx above the vocal cords. It, however, occasionally extends below the cords affecting the trachea and bronchi. In rare cases, it is limited to that part of the larynx below the vocal cords, in which case it is known as the sub-glottic variety. This form of the disease was recognized by Sestier, Cruveilhier, and Gibb, and of the 96 cases I find that 2 are of the sub-glottic variety: in one, reported by Gibb,[1] in a man thirty years of age, who had an inflammation of the cricoid cartilage due to traumatism, a resulting abscess caused edema of the sub-glottic space; in the other, reported by Lefferts,[2] in a boy five years of age, the disease followed exposure to cold. Both patients recovered.

The vocal bands are very rarely affected, as they contain very little cellular tissue. However, I find 2 cases recorded. In one reported by Natier,[3] the infiltration was due to tuberculosis; in the other, reported by Semon,[4] the edema was due to excessive use of the voice.

The order of frequency of the parts affected in my list of cases was: the epiglottis alone in 7; epiglottis and ary-epiglottic folds in 14; ary-epiglottic folds alone in 5; soft palate and ary-epiglottic folds in 3; arytenoids and vocal bands in 1; right arytenoid in 1; arytenoids and commissure in 4; vocal bands alone in 2; right arytenoid and corresponding ary-epiglottic fold in 1; epiglottis and arytenoids in 1.

The disease is generally bilateral, but occasionally it affects only one-half of the larynx. Feiber[5] describes a case in which the edema was contiguous to an acute pharyngitis, and in which the infiltration was limited to the corresponding half of the larynx. S. Solis-Cohen[6] reports two cases, both of traumatic origin, and Lefferts[7] one case that followed exposure to cold.

Acute edema of the larynx occasionally sets in with such suddenness that no warning is given, and the patient dies before aid can be rendered. Generally, however, the onset is more gradual, and the patient complains of a sensation as of a foreign body in the throat, the removal of which he attempts by swallowing and by the insertion of the finger in the throat; deglutition is painful and difficult, the voice is altered in timbre, dyspnea is always present, and the inspirations are frequently accompanied by a whistling, stridulous sound, especially when the ary-epiglottic folds are the seat of the infiltration. The patient is restless and has an anxious expression, and unless relief is obtained the face becomes cyanotic, and death results from asphyxia.

The diagnosis of this affection is not difficult: the symptoms of stenosis, in connection with the dyspnea and the alteration of the voice, indicate the larynx as the part affected, and by means of the laryngeal mirror the nature of the affection is at once revealed. The tumefied parts are red, though sometimes translucent and pale-yellow in appearance. In the absence of the laryngoscope, exploration with the index-finger as recommended by Tuilier can be practised, when the swollen epiglottis or ary-epiglottic folds can be felt. Great care must be exercised in carrying out this procedure for fear of causing suffocation.

Although acute edema of the larynx is a very serious affection, the prognosis is now not so unfavorable as it formerly was, owing to the practice of scarifying the swollen parts, and also to the early performance of tracheotomy when indicated. Sestier found that of 213 cases 158 proved fatal, in spite of tracheotomy having been performed in thirty. Bayle gives much more unfavorable figures, as 16 of his 17 cases proved fatal. Kühn (quoted by König[1]) collected 95 cases, 36 of which were fatal. Of the 96 cases that I have collected, the disease proved fatal in 34, giving a mortality of 35 per cent., which is a little less than that given by Kühn. The prognosis must be greatly influenced by the cause of the edema and by the intensity of the inflammation, as well as by the age and sex of the patient. That form due to an extension of inflammation from the pharynx generally does well when taken in time, but when the inflammation is due to erysipelas, or to constitutional causes, such as typhoid fever, septicemia, and pyemia, the chances are extremely unfavorable. The disease is more serious in men than in women, while the greatest mortality is in cases between ten and forty years of age.

Prompt local measures must be employed in order to relieve the obstruction to respiration. In no severe disease is there such speedy relief obtained by means of a simple operation as in acute edema of the larynx from scarification of the swollen parts. Sometimes the relief appears almost magical. Proposed and practised by Lisfranc in 1825, scarification did not receive the recognition of this eminent surgeon's colleagues, probably, as suggested by Dr. Bartlett,[2] on account of jealousy. We even find Cruveilhier,[3] a number of years later, saying he

[3] Dict. de Méd. et de Chir. pratique, "Laryngite," xi, 41.

"doubts whether this little operation of scarification has ever been performed." It was not until 1847, when the late Dr. Gurdon Buck,[1] unaware that scarification of the epiglottis had been previously performed by Lisfranc, practised it at the New York Hospital, and owing to his series of successes the operation became a popular one. It is best performed with the laryngeal lancet, with the aid of the laryngeal mirror, but in the absence of these it can be effected with the ordinary curved bistoury, covered, except for the last quarter-inch of its length, with adhesive plaster. After scarification, gargling with warm water will greatly facilitate the expulsion of fluid from the tissues. The cold coil or an ice-bag should be placed over the larynx, and the patient be directed to swallow cracked ice frequently. This, in conjunction with the hypodermatic injection of pilocarpine, as first proposed by Gottstein,[2] will hasten the absorption of the fluid and often prevent a recurrence of the edema. The atmosphere of the room should be rendered moist by boiling water containing the compound tincture of benzoin. Inhalation of astringents will often assist in the absorption of the infiltrated fluid and the restoration of the inflamed membrane to health.

If, in spite of the scarification, the edema continues and the dyspnea increases, then tracheotomy should be performed without further waiting. The lives of many patients have been saved by the early performance of this operation; and remembering the liability of the edema to extend into the trachea, it is best to operate low down, making sure that the knife has entered the trachea, so that the tube will not pass between the swollen mucous membrane and the wall of the trachea—an accident that has happened to good operators.

Intubation has been successfully practised by Desault,[3] Macewen,[4] Meier,[5] Ingals,[6] and Altamirano,[7] but it has not been performed often enough for any estimation of the value to be placed upon it as a substitute for tracheotomy. Its efficiency, of course, depends upon the part of the larynx that is edematous. Ingals refers to one case in which the obstruction to respiration could not be relieved by the laryngeal tube. It would seem, however, that cases of chronic edema and those acute cases in which the edema is moderate in degree and in which there is danger of paralysis or spasm of the posterior cricoarytenoid muscles, such as in the unfortunate case reported by J. Solis-Cohen,[8] are best suited for intubation.

CONTRIBUTIONS TO THE STUDY OF HETEROPHORIA AND ITS RELATION TO ASTHENOPIA, HEADACHE, AND OTHER NERVOUS SYMPTOMS.[1]

By SWAN M. BURNETT, M.D., Ph.D.,
of Washington, D. C.

I assume that at least all but a very small minority of the members of this Society recognize the existence of a condition of disturbed equilibrium of the external ocular muscles that gives rise to well-marked symptoms of asthenopia, headache, and other nervous symptoms; I also assume that we have not as yet reached the last word on the therapeutics of these conditions, and that we are all desirous of accumulating trustworthy evidence on the merits of the different methods that have been proposed for their relief. I can say in support of this, my humble contribution, that the observations have been made with a mind free from bias or prejudice, and the facts recorded with honesty.

I have used the terms heterophoria, exophoria, esophoria, etc., introduced by Dr. Stevens, because they are short and distinctive, and designate, with sufficient exactness, the actual conditions.

I have not found heterophoria of so common occurrence as has been reported by some observers. For a number of years I have, with few exceptions, tested every case of optic defect that came under my observation in private practice, for a disturbance of equilibrium in the external muscles, and taking 100 cases at random in my case-book, I find that among that number there were 22 in whom heterophoria of some kind and degree was present. In most of these no attempt was made to correct the fault, either because the patient was not seen again, or because the correction of the other ocular difficulties gave all the relief that was desired. Heterophoria does not, any more than ametropia, always give rise to asthenopia or call for correction; and I am, from my own observation, inclined to believe that heterophoria of even small degree is rarer than ametropia—that is, that human eyes are more normal in regard to their muscular equilibrium than to their optic condition.

We are not yet, I am free to confess, in a position to generalize and formulate positive dicta in the matter, but my experience would lead me to infer that an exophoria or an esophoria of two prism-diopters in persons of average health does not, usually, give rise to trouble on ordinary use of the eyes; hyperphoria of that amount, I think, does. Moreover, the defect is a quantity constantly varying with the condition of the patient, so that we must allow ourselves considerable latitude in estimating its actual and permanent amount. It is this fact, probably

[1] Read at the meeting of the American Ophthalmological Society, held at Washington, September, 1891.

beyond all others, that lies at the foundation of our difficulties in therapeutics.

I examine the equilibrium always at an infinite distance, the eyes being then in a condition of accommodative relaxation and in a state of practically normal parallelism, or at least in a condition of normal muscular inertia.

In testing, I use the flame of an Argand burner in my ophthalmoscopic room, six meters away, turned low, and produce diplopia by means of an eight-diopter cylinder. This has all the advantage of the Maddox prism, with the additional advantage that, by moving the lens at right angles to its axis, the very much elongated image effected by the cylinder moves up and down or laterally, enabling patients who are not very ready at observation to tell at once the relative position of the gas-jet and the streak of light—that is, whether the latter passes through the flame or to one side. On the black wall of the ophthalmoscopic room I have ruled white squares with six centimeters between the lines; opposite the center of the system of squares I place the flame of the Argand burner. The patient can then indicate, if there be any diplopia, the number of squares that separate the light-streak, and the side on which it is from the flame. At the distance of six meters each square of six centimeters represents one prism-diopter of deviation, and thus the number of spaces of separation gives the degree of heterophoria expressed in the number of the prism necessary to correct it; and the side on which the light-streak is seen gives us knowledge of the kind of heterophoria.

I consider the test at an infinite distance the necessary one, and that at the working distance less important because less reliable. It is common to find quite a considerable heterophoria at a distance, and yet none with the dot-and-line test of Gräfe. The accommodation comes in here to vitiate the result. The power possessed by the individual muscles, as expressed by their ability to overcome prisms, I do not rely on so much as I formerly did. The power of overcoming prisms is one of education largely, and, while not unduly depreciating the method, I consider it inferior to the test at infinity. It is here that the real relative power of the muscles is shown, and that is what we want to know. I do not deny the possibility of the existence of a positive weakness of the interni that will give a separation of the double images in convergence, which is not apparent at the test at infinity; but I think such a condition must be rare.

Another point on which we are in need of statistical investigation is the relative frequency of esophoria, exophoria, and hyperphoria. Formerly, insufficiency of the interni was considered the sole cause of muscular asthenopia—as it was called, to distinguish it from that due to accommodative strain—and I think we have all been surprised to find how often weakness of the externi is the cause. Dr. Noyes, as is well known, has found this condition the more frequent of the two.

I find that among 50 recorded cases of heterophoria taken in succession from my case-book, there were 28 cases of exophoria, 18 of esophoria, 3 of hyperphoria, and 1 of combined esophoria and hyperphoria.

Coming now to therapeutics, there are, of course, only two methods of treatment, if we recognize the existence of heterophoria apart from ametropia, and these methods are: prisms, and operation on the muscles. All cases of heterophoria do not demand correction for the immediate relief and comfort of the patient any more than all cases of ametropia do; but there can be no question that in the one case as in the other such correction will place the patient in a much better condition ocularly, and probably forestall a future break-down. But there is, unfortunately, a large, suffering class, clamoring for relief, and it remains for us to choose between these two methods of cure.

It would seem, at first blush, that prisms would fill all indications, and that we had only to select the prism that appears to correct the faulty position of the double images and the difficulty would be overcome and the desired relief obtained. In this, however, our hopes are often blighted. In some cases, it is true, we hear no further complaint, and the prisms are worn with perfect satisfaction. In another contingent of cases, the relief is only partial, and in many others no benefit at all is experienced.

It has heretofore been assumed by practical ophthalmologists, and, I think, by all physiologic opticians as well, that, theoretically at least, the prism is able to correct optically all of the difficulty. Though the prism is the simplest of all optic instruments except plane glass, it does not seem to be remembered by these that its optic properties are not a little complex, even under the conditions that usually prevail. Physicists, however, have for a long time been aware of these phenomena, and have treated of them mathematically, and a full consideration of the subject can be found in the recent works of Heath[1] and Aldis.[2]

In order that light be deviated by a prism in accordance with the well-known laws laid down in our ordinary treatises, the pencils must be parallel. When they become divergent, not only do these laws become modified in such a manner that deviation for the divergent is less than that for parallel

[1] R. S. Heath: Geometrical Optics. Cambridge, 1887.

[2] W. Steadman Aldis: Elementary Treatise on Geometrical Optics. Third edition, Cambridge, 1888.

pencils, but, in addition, the prism exercises a demonstrable astigmatic action—that is, a point from which the rays fall divergently on a prism has, after their passage through the prism, a focal interval of Sturm in which, however, the focal lines are not, as in sphero-cylinders, straight, but of a peculiarly curved form. Moreover, it has been found that the thickness of the prism itself cannot be wholly ignored, as we have been accustomed to do, and that the refraction is different at its apex and base. It is only in prisms of five prism-diopters and less that the accepted laws of prismatic refraction apply.[1]

Then, again, there is the annoyance almost always experienced in getting accustomed to the use of prisms—a difficulty that is overcome only in many instances after a long period of education, and sometimes not at all. And furthermore, there is a class of patients that protests strenuously against the use of spectacles of any kind. There are many women who would rather submit to any number of tenotomies than wear glasses for a week. And we must remember, too, that the wearing of glasses is a burden and a great inconvenience, and in not a few instances a handicap in the race of life. We have so accustomed ourselves to the inevitable spectacles in correcting ametropia that we do not sufficiently recognize that in heterophoria there is an alternative; finally, there are those cases in which prisms do not give the desired relief. If, then, we shall determine that heterophoria is correctable by an operation, that operation will and should be the rule, and the use of prisms the exception.

The correction of disturbance of muscular equilibrium by tenotomies is now on trial in this country, and evidence in its favor is constantly accumulating. Beyond the sea, so far as my knowledge extends, nothing of any consequence is being done in that direction in advance of what was accomplished by Gräfe, whose work was directed wholly against the insufficiency of the interni in myopia. One explanation of this may be, that they do not have the amount of asthenopia from the same cause there as we do here.

Like nervous prostration, I think the asthenopia of ametropia and heterophoria is a disease developed largely by the American method of living, which, however, on that account is none the less a disease requiring at our hands the most careful consideration. If tenotomy will restore the lost equilibrium of the muscles, it is certainly the most scientific, the readiest, and in every way the most commendable method of dealing with the difficulty. My own experience with the operation is somewhat limited, but could have been greater had I been less conservative and cautious. The results, however, have been eminently satisfactory and such as to convince me that not only is it a legitimate operation, but one that, under certain circumstances, is imperatively demanded.

As briefly as possible I will give the salient points in the histories of five cases in which I have done the operation of partial tenotomy.

Case I.—Miss J. H., a Western girl, "with no nonsense about her," aged nineteen, was seen first December 13, 1889. She had been struck on the right eye by a stone when eight years old and there is a remaining scar on the cornea on the outer margin. Vision, however, was the same as in the other eye, namely $\frac{5}{9}$, which with +0.75, 100° R. and +0.5, 80° L. became $\frac{5}{6}$. The keratometer gave L. 155° 44 D. 15° × 1, R. 75° 44 D. 150° × $1\frac{1}{4}$. She had suffered so much from her eyes and head that it had been impossible for her to get any systematic education. Any use of the eyes would give her a violent headache. She was treated for a long time by one of the best ophthalmic surgeons in the West, but with no permanent relief. The muscular equilibrium had not, however, been tested until she came to me. I found that she had at the first examination an esophoria of 5 P. D. She fused 5 P. D. base in and 20 P. D. base out. On the 16th her esophoria was 7, and on the 24th 8°. She was given R. +0.75, 100° prism No. 4, base out. L. +0.5, 80° prism No. 4, base out. From the use of these glasses she experienced some relief, but she was still unable to use the eyes with any degree of regularity or reliability. On June 17, 1890, the esophoria was 10 P. D., and on the 18th 12 P. D. I then advised a tenotomy and it was readily acceded to, the patient being willing to submit to anything for relief. Accordingly, on the 23d I made a partial tenotomy of the right internus, correcting the esophoria to 4 P. D. On July 9th she was ordered R. 3 P. D. base out, L. 1 P. D. base out, and went away for the summer. She used her eyes all summer in fair comfort, getting more use of them in three months, she said, than in any three years before. She came home and went to hard work and her eyes began to trouble her again, and her prisms did not afford her the desired relief. I then made another partial tenotomy of the same muscle on October 22d, leaving only a few fibers above and below. The correction was complete for an instant, the images then separating somewhat, homonymously. In a few days this settled down to 2 P. D., at which it has remained approximately ever since. She has been able to use her eyes with comfort most of the time since; has continued her musical studies, and sews and reads as she has never done before in her life. As she says herself, "It has made a new girl of me," and certainly her general appearance is vastly better than before the operation.

Case II.—Miss Annie B., a stout, healthy-looking girl, aged seventeen, was first seen March 23, 1886. She had at the time myopic astigmatism, R. —2 ◯ 0.5,90°; L.—1.5◯—0.5,90°. No note is found that the muscular equilibrium was examined at that time.

[1] Mr. C. F. Prentice has given a graphic representation of this. American Journal of Ophthalmology, Oct. 1891.

She returned on February 25, 1889, with serious complaint of her eyes and head. She looked worn and haggard, and her headache was almost constant and had been for eighteen months. The myopia had increased in the right to —5 D., and there was at the first examination an exophoria of 4 P. D. She fused 4° base in, 14° base out. She was ordered the prisms in addition to her ametropic glasses, but they were not at all satisfactory. She had a little less pain when she used them than when she did not, and the exophoria had increased to 8 P. D. I advised a tenotomy, and it was done on November 13, 1889. The exophoria was reduced to 3°. This varied from time to time, being sometimes more, sometimes less, until it finally settled at 3° on November 26th. On the 6th of December she reported that she reads all she wants to without pain and that her headaches are gone. On January 28, 1891, she had an attack of asthenopia and the old pain in the head from overwork, and the exophoria was 4 P. D., and we thought we might have to make a tenotomy; but a few days' rest relieved it, and she has been in comparative comfort ever since.

CASE III.—Miss C. W., aged twenty-one, I first saw April 24, 1887. She complained of great pain from the use of her eyes, which went from the back of the eyes to the back of the head and neck. She had suffered then for a year and had done everything for it. Her vision was $\frac{5}{5}$ and there was no ametropia. She fused 3° base out, 21° base in, and there was an exophoria of 5° or 6°. She was given: R. 3° base in, L. 2° base in. I heard nothing more from her until January, 1891, when she came to me from her physician with a request that her eyes be examined again. She had been wearing the prisms ordered nearly four years ago and with some relief at first, but the headaches had lately become so constant and intense that life was a burden. She was willing to submit to anything that promised relief. Her exophoria was 8 P. D. She accepted the proposition for a tenotomy readily, and I made it January 31st, reducing the defect to 2°. On February 4th it was 4°, on the 10th 4°, and on the 14th 6°. The relief was at the time very marked. I saw her no more until June, when she returned with the old complaint. I found that the exophoria was again 8 P. D., and the red glass gave double images, the result of the first operation being *nil*. Another partial tenotomy was made on the right eye on June 13th, this time cutting away a triangular piece of the middle of the tendon. I allowed at this operation an over-correction of 1 P. D., which remained after a conjunctival suture was applied. On the 10th the stitch was removed and complete correction was found, the false image varying however sometimes a little to the right and sometimes to the left. On the 18th the exophoria was 2 P. D., on the 22d 1½ P. D., and on the 26th 26 P. D. She then went away for a vacation, her nervous system being a total wreck.

CASE IV.—Mrs. I. D., a lady aged fifty-eight, five years ago had some trouble with her head that was diagnosticated as congestion of the brain. Not long afterward she noticed that her eyes pained her on use and that headaches were frequent. These symptoms increased and for three years she has been unable to use her eyes at all. The reading of more than a dozen lines of print at one time is impossible and she has accustomed herself to write with her eyes shut. Her general health seems to be good and she spends the greater part of her time out of doors in the country. Her disease was considered retinitis by an oculist under whose care she had been for a long time past, and the prognosis was regarded as grave. There was no evidence of retinitis apparent at the time of my examination, and with $+0.75\ \mathrm{V} = \frac{5}{6}$ in R., and with $+0.75 \bigcirc +0.5$, $90°\ \mathrm{V} = \frac{5}{6}$ in L. A necessarily hasty examination at that time revealed an exophoria of 5 P. D. at infinity, and a much greater one for the working distance. A red glass before one eye produced diplopia. The nature of the trouble was explained to her, and she was encouraged to believe an operation might relieve her if the glasses (3° base in, R., 2° base in, L.) did not lead to a satisfactory improvement. She reported by letter, from time to time, that the prisms were beneficial, but the relief was not perfect, and finally she came down on May 9, 1891, to have the operation performed. The exophoria was then 10 P. D., as it was on the 12th when the operation was performed. She was able to fuse 1 to 1½ P. D., base out. I made a tenotomy of left externus, leaving a few fibers above and below, and the correction was well-nigh perfect. I then cut out a small triangular piece of the tendon between these attached fibers. I did this in the belief that a greater diminution of power would follow its reattachment on account of its diminished length. Immediately after the operation, she fused 2 P. D. base in. On the 13th she fused 3 P. D. and a 3 P. D., base in, superposed the images. On the 15th, 2 P. D. superposed them, though there was a great deal of unsteadiness, as there was indeed until she left for home on the 17th. On that day, however, she read several pages without fatigue. I have not seen her since, but the value of the operation in her case can best be expressed by an extract from a letter which she wrote me some four weeks after the operation: "You will remember that before going to you I could do absolutely nothing that required the use of my eyes, without pain in both head and eyes so great that I would be obliged to stop in a few minutes. When I first came home there would be some sense of strain, some little quivering sensation after reading or sewing for a while; this has gradually passed off, and I now read or sew or write as long as is convenient—as much as three or four hours at a time." Naturally such a result as this is not likely to lead me to an early abandonment of partial tenotomy in heterophoria.

CASE V.—Miss H. J. B., aged twenty, a sister of Case II, I saw for the first time on July 25, 1891. She is a strong young woman, both mentally and physically, but had been obliged to give up her studies at Wellesley College on two occasions for a year on account of persistent headache, confined almost exclusively to the occiput and back of the neck. For this she had tried all sorts of things, but with no avail. She would often be disturbed in the night by the pain, and it was commonly present

on waking in the morning. As her vision was good, she did not connect the pain with her eyes, but only came to have her eyes examined as a *dernier ressort*, and with a hope that something might be found the correction of which would relieve her of her burden. She is emmetropic, the ophthalmometer showing only the normal corneal astigmatism and V = $\frac{5}{5}$. She had at the first examination a manifest exophoria of 7 P. D. The next day it was 8 P. D. I gave her No. 3 prisms for each eye, to be worn during my vacation. I saw her next on the 6th of September and the manifest exophoria was 10 P. D. The prism had given some little relief, but she was more than willing to have a tenotomy performed, and this I did on September 9th, on the right eye, leaving some fibers above and below, but excising a piece of the middle portion. The exophoria was reduced immediately to less than 2 P. D., and the false image in the test would sometimes be directly above the true image. It varied but little from day to day and has finally settled down to 2 P. D. She fuses 5 P. D. base out, and in the test at the working distance there is no demonstrable insufficiency. This was only two weeks ago, and the headaches are already much improved.

A word or two in regard to the technique of the operation. It has been doubted in some quarters whether a permanent weakening of the muscular power can follow a division of less than the whole of the fibers of the tendon. In some cases it would seem that after the final healing of a single operation the heterophoria was little, if at all, diminished. To what the failure is due is not always apparent. I have thought it possibly caused by a want of sufficient retraction of the divided fibers, and have sought to compensate for this by an excision of a portion of them. The results, in the cases in which I have done this, have appeared to justify the procedure. Some, and among them Dr. H. D. Noyes, have favored a total separation of the fibers and a subsequent regulation by means of sutures. This would undoubtedly accomplish the purpose in view, but it seems to me that the risk of malposition of the tendon in the new insertion is very great in this plan. A slight rotation of the globe in adjusting the sutures might easily bring about such a change in the relative position of the eyes as to render the later condition of the patient much worse than the first. This danger of an improper reattachment of the muscle is one to which I think we have not paid sufficient attention, and it has induced me to modify my operation for advancement by leaving a few lateral fibers attached and advancing the tendon along the line of its central fibers. Dr. G. T. Stevens has considered this question in his last paper in Knapp's *Archives*, July, 1891.

The therapeutics of heterophoria by prisms has been treated of in so thorough a manner by so many competent authorities that its consideration here by me would unnecessarily increase the length of this paper, already over-long. In many cases I have found prisms satisfactory, especially when the heterophoria was of low degree, but in a large number of instances their use did not bring the relief desired, and almost never when the heterophoria exceeded 4 P. D.

Among the exceptional cases is the following:

CASE VI.—Miss C. N. T., aged eighteen, has been suffering from violent headaches for a number of years, and they have been almost constant during the last twelve months. Her vision is $\frac{5}{5}$; no ametrophia. She fuses 5 P. D. base down, 1 P. D. base up; has a hyperphoria of 6 or 7 P. D. Diplopia caused by red glass before one eye. I advised a tenotomy, but it was refused, and I ordered 3 P. D. base up in R., 3 P. D. base down in L. With these she has been using her eyes in fair comfort, with only one breakdown, from over-study, since January of this year. It is more than likely, however, that a tenotomy will yet have to be done.

Note, January 22, 1892.—As some time has elapsed since the foregoing histories were made, a report of the present condition of the patients will add to the interest and value of the statistics.

Case I is doing well, and has no cause of complaint on the part of her eyes or head, except that she is not able to read as much as she likes, which would be almost continuously. Other work, such as sewing, writing, and music, give her no trouble.

Case II reports that she has only an occasional headache, which can be referred to causes not connected with the eyes.

Case III returned from her short vacation still in a run-down condition, and with headaches on any effort of any kind. She is one of those unsatisfied, uncontrollable patients who demand immediate relief. She went under the care of another physician, who "treated the origin of the eye trouble in the general system," and did nothing for the eyes themselves. In time she began to improve in general health, and after a while the headaches disappeared. I have no hesitation in giving the tenotomies the credit of whatever permanent relief she has experienced. In patients as exhausted as she was, it takes weeks or even months for a full recovery to be effected.

Case IV still continues to use her eyes as she wants to with ease and comfort.

Case V has been doing work during the last three months that would have been impossible for her to have done before, and with only a moderate degree of discomfort. The headaches in the morning are gradually going off.

In Case VI I finally made tenotomies, as I felt sure I should have to do. She came complaining of some headache and pain in the eyes when she used them for any length of time. The prisms, though helpful, did not give permanent or constant relief. I first tenotomized the superior rectus of the left eye, reducing the hyperphoria to 4 P. D. Two weeks later I operated on the inferior

rectus of the right eye, getting complete correction. Four weeks after the last operation she writes that the relief has been complete, and that she has no trouble at all.

ELECTRO-PUNCTURE—ITS MOST USEFUL MODIFICATIONS AND ITS VALUE IN THE TREATMENT OF FIBROID TUMORS.[1]

BY G. BETTON MASSEY, M.D.,

PRESIDENT OF THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION; INSTRUCTOR IN ELECTRO-GYNECOLOGY IN THE PHILADELPHIA POLYCLINIC, ETC., PHILADELPHIA.

THE method of inducing atrophy of myo-fibromata of the uterus by currents from electrodes introduced into the substance of the tumors by puncture deserves special consideration, from the fact that it is essentially a bolder and more radical procedure than the other electric methods of dealing with these growths. Gynecologists who use electricity are greatly divided as to its value and freedom from risk, some rejecting it altogether, and others considering it the only method worthy of use. My own position in the matter has been represented as that of warm advocacy of puncture—a statement that was a surprise to me at the time, although I have recently had reason to look on the procedure under certain conditions and circumstances with increasing favor.

There is no doubt that this method presents itself with much favor to the beginner in the treatment of fibroid tumors, and I think this is often because tyros have the false impression that electricity acts in these growths by dissolving them. No error could be greater, and it is a mistake that is likely to lead to harmful work in the direction of over-treatment. It is true that we do not know the mode in which electro-puncture does act, but my observation has convinced me that the period between treatments is an essential part of the treatment itself, to be carefully arranged in each case, and that results are not proportionate to current-strength alone. These two facts, when taken together, certainly indicate that electricity does not accomplish the reduction and dissipation of fibroid tumors by electrolysis pure and simple, because this is a chemical disintegration depending in extent only on the number of millicoulombs used. Were this the method of its action, by an increase in the current it would be possible to dissolve the tumor at once and at one application. In the cases under my observation in which the tumors have disappeared,[2] no such currents were used. The current-strength was frequently smaller than that used in tumors that did not disappear. However we may explain it, it is certain that the absorbents bear an important relation to a shrinking fibroid after each electric séance, and that mere electrolysis is but a part of the work, and a part that may be subordinate to a more subtle interference with tissue-integrity and metamorphosis.

From experience I am not disposed to think that puncture presents necessarily any advantages over intra-uterine applications when either method is feasible. In certain cases apparently well adapted to both methods I have observed that puncture was better, but this seemed to be due to irritative conditions of the appendages that hindered or nullified the good effects of the intra-uterine applications. In such cases the punctures were much better borne, and produced no reaction.

VAGINAL ELECTRO-PUNCTURE.

Speaking of vaginal puncture alone, and premising that it should never be performed unless a portion of the tumor can be reached directly through the posterior vault, it may be said that the spot punctured is accessible and may be kept under rigid antisepsis, which is a distinct advantage over the prolonged application of a strong current to a restricted spot within the uterus.

As to the method of performing vaginal puncture, I have urged from the beginning that the trocar should be insulated through the healthy tissue in order that the latter may heal at once. This may be called *buried puncture*, in contradistinction to that of Apostoli. Not wishing to make a patulous opening or to have a possible slough at the point of application, both of which I believe are liable to occur at the positive pole, my punctures have been almost invariably negative. To meet these indications I have recently modified the specially insulated trocar formerly employed, and now use one of steel, combining certain features of my own and some of Apostoli's latest pattern. The one exhibited to you has, as you see, the shoulder now employed, I believe, by Apostoli, to prevent the instrument being inserted beyond one-half centimeter, but in this case the shoulder is one and a half centimeters from the point, permitting a possible insertion to the latter depth. Only the first half-centimeter from the point is exposed for the electric action, the remaining centimeter being covered by hard rubber that is flush with the needle-point, the diameter of the needle here having been lessened. The rubber insulation is vulcanized on the shaft, and presents a continuous insulation from the point to the attachment-socket at the posterior extremity. This has been the most satisfactory instrument thus far used by me, being strong and stiff, free from impedimental handles and sheaths, and incapable of being

[1] Read at the first annual meeting of the American Electro-Therapeutic Association, September 25, 1891.

[2] For a report of five such cases see Annals of Gyn. and Ped., July, 1891.

inserted more deeply than intended. It can be made aseptic by boiling, and I have even employed the spirit flame when prepared to remedy any damage it might cause to the insulation.

As I said before, buried vaginal puncture will reduce fibroids and remove pain when the intra-uterine method is not tolerated. I have, morever, never had a mishap or bad effect from its use, and have had pain following it on but one occasion, which was possibly due to a dispensary patient walking some distance home within an hour after the puncture. This freedom from mishaps I nevertheless attribute almost entirely to a careful selection of cases, as I can well conceive that the procedure would risk injury to important organs if employed in any case other than those in which the tumor is accessible by virtue of a practical protrusion into the posterior vaginal vault.

ABDOMINAL ELECTRO-PUNCTURE.

There is another form of buried puncture to which I wish to direct your attention particularly. I allude to insulated puncture through the abdominal wall. Abdominal electro-puncture has been condemned by myself, in unison with recent workers in electro-gynecology, but the thought occurred to me some months ago that my condemnation was of that unwise kind that precedes a trial, and that the bad results reported in the past occurred in pre-aseptic days. There are certain abdominal tumors of large bulk that are so far removed from the pelvic extremity of the cervix and vicinity of the vagina as to make intra-uterine treatment difficult, tedious, and painful, and vaginal puncture impossible. These tumors are beneath our hands externally, with nothing but a layer of fat and muscle and two layers of peritoneum intervening. As contrasted with the pelvic route, puncture from this direction is free from the embarrassing neighborhood of important organs, is direct and exact, but possesses the one disadvantage of being intra-peritoneal. Experience in two cases which have been punctured on several occasions, has convinced me that the peritoneal bugbear is overdrawn, at least when aseptic precautions are observed. Peritonitis and its effect, adhesion, can only follow the introduction of septic material, or a possible necrosis from a too strong positive puncture.

The details of the procedure as devised by me are as follows: The punctures being invariably negative, small steel needles are used, three at each puncture, attached by branched wires to a single pliant copper wire as a conducting cord. No. 22 or 24 insulated wire is much more convenient than an ordinary conducting cord. For the puncture-needles there can be no better form devised than the straight Hagedorn surgical needle found in every instrument-shop. These needles possess the advantage of great ease of penetration combined with lightness and strength, and the slit puncture made by them admits the increased bulk of the covering without hitch. This slit form of puncture also heals easily without a scar. The needle should be about two and a half inches long, the first half-inch from the point being left bare, and the portion above covered with hard rubber, vulcanized on the shank as thinly as consistent with good insulation. It is easily attached to the copper wire by the latter being passed through the eye and wound around the shank—by simple threading, in other words—or the needles may be permanently soldered to cord-tips, as suggested by Dr. Walling. These needles, properly insulated, sterilized, and attached to the negative pole of the battery by the branched wire, are easily and painlessly thrust into the tumor through the skin, the surface having been previously thoroughly asepticized by the most approved method, and just before the insertion of the needle chilled by a rhigolene spray. The current-strength has varied in my punctures between 60 and 100 ma., and the duration from six to eight minutes. After removal of the needles the minute spots made are sealed with a little borated cotton and plaster, or by the direct application of collodion.

As to frequency, it is probably best to allow at least two or three weeks to elapse between each application of electricity in this manner, although this depends on the size of the tumor and the field of tumor-surface accessible to the method. It need scarcely be said that no punctures should be made at any spot that might be covered by intestinal convolutions.

The immediate inconveniences that follow these punctures, such as tenderness and pain, are generally less than those following an intra-uterine application. As a measure of precaution, one patient under this treatment was kept in bed in the Sanatorium for twenty-four hours after each puncture, but another was punctured at the dispensary, and on each occasion walked home shortly afterward. In neither of these cases has sufficient time yet elapsed to permit a full determination of results, but in each case there has been a marked decrease in size, and in one case a lessening of the pain that had rendered the patient helpless. There has not been an unfavorable incident of any kind, and the absence of adhesions between the tumors and the abdominal walls is easily proved. The result, in my opinion, is to open anew the question of the propriety of employing buried abdominal electro-puncture in the treatment of those large fibroid tumors, both intra-mural and subperitoneal, that lie above the pelvic brim.

MICROCOCCUS PNEUMONIÆ CROUPOSÆ.

BY GEORGE M. STERNBERG, M.D.,
LIEUT.-COLONEL AND SURGEON U. S. ARMY.

SYNONYMS: *Microbe septicæmique du salivé* (Pasteur); *Coccus lancéolé* (Talamon); *Micrococcus Pasteuri* (Sternberg); *Pneumococcus of Fraenkel; Diplococcus pneumoniæ* (Weichselbaum); *Bacillus salivarius septicus* (Flügge); *Streptococcus lanceolatus Pasteuri* (Gamaléia).

The object of the present brief paper is to call attention to the earlier researches relating to the important pathogenic micrococcus to which it refers. This seems desirable at the present moment, inasmuch as the distinguished author of the Croonian Lectures, recently published in *The Lancet*, has given an account of the history of the micrococcus in question, in which he fails to recognize my priority in its discovery. He says:

"Its history is as follows: In 1881, M. Pasteur observed, to his surprise, in inoculating a rabbit with the saliva of a child affected with hydrophobia, that the animal died rapidly of septicemia. Subsequently Dr. Sternberg, of Washington ('Der Mikrokok der Sputum-septikämie,' *Deutsche med. Wochenschrift*, 1887, p. 44), having observed that the inoculation of pneumonic sputum induced in the rabbit symptoms similar to those observed by Pasteur ('Note sur une maladie nouvelle provoquée par la salive,' *Bull. de l'Acad. de Médecine*, 1881), repeated the experiment with his own saliva. As this animal also died of septicemia, he was led to investigate the subject bacteriologically, and found that in all the animals inoculated the same microzyme occurred, and that it corresponded with Pasteur's description of the *Microbe septicæmique du salive*." (Quoted from *The Lancet* of November 28, 1891, p. 1209.)

Now, as a matter of fact and of record, the present writer discovered the micrococcus in question in the blood of rabbits inoculated with his own saliva, in the city of New Orleans, in September, 1880, three months before Pasteur discovered it (December, 1880) in the blood of animals inoculated with the saliva of a child that died of hydrophobia in one of the hospitals of Paris.

At the date referred to I was not able to follow up my experiments immediately, as I was engaged in another investigation. But they are recorded, with the date upon which they were made, in my special report to the National Board of Health, on "Experimental Investigations Relating to the Etiology of the Malarial Fevers," which was submitted some time before the publication of Pasteur's note referred to by Dr. Burdon-Sanderson, and was published in the *National Board of Health Bulletin*, vol. iii, Washington, 1881–2.

Impressed with the surprising fact that my saliva contained a pathogenic micrococcus that quickly proved fatal to rabbits inoculated with the fluid containing it, I went to Philadelphia in January, 1881 (before the publication of Pasteur's first communication), for the express purpose of making further investigations with reference to this micrococcus in the laboratory of the Medical Department of the University of Pennsylvania.

"Here eleven inoculation-experiments demonstrated (*a*) that the virulence noted was not due to season or locality, as the same result followed inoculations made in Philadelphia during the winter months as had been obtained by similar inoculations in New Orleans during the heat of summer; (*b*) that this virulence was not an individual peculiarity, inasmuch as eleven rabbits inoculated with the saliva of six different persons, gave eight deaths and three negative results."

In March, 1881 (still before the publication of Pasteur's first communication), I resumed my experiments in the biologic laboratory of Johns Hopkins University, Baltimore, and by the inoculation of pure cultures obtained from the blood of infected rabbits, proved that the fatal septicemia induced in rabbits by inoculating them with my saliva was, beyond question, due to this particular micrococcus. I also determined many of its biologic characters, accurately described its morphology, and made photo-micrographs showing it in the blood of an infected rabbit. The results of this investigation are published in my paper on "A Fatal Form of Septicemia in the Rabbit, Produced by the Subcutaneous Injection of Human Saliva" (*National Board of Health Bulletin*, vol. ii, 1881; also, *Johns Hopkins University Stud. Biol. Lab.*, Baltimore, vol. ii, 1882, pp. 183–200, 1 pl.)

The publication of this paper was considerably delayed after I had completed my research, and in the meantime Pasteur had published his "Note sur une maladie nouvelle provoquée par la salive," referred to by Dr. Burdon-Sanderson.

My earlier researches were followed by others, in which I used this micrococcus as a test of the comparative value of various disinfecting agents,[1] and in the course of which I determined various points relating to its biologic characters.

In January, 1885, I made a series of experiments with pneumonic sputum, which led me to the identification of the oval coccus, usually in pairs, found in this material, with the micrococcus previously

"Germicide Value of Therapeutic Agents," Amer. Journ. Med. Sci., Phila., 1883, pp. 321–343.

isolated from my own saliva. In the paper[1] in which I gave an account of these experiments I named the micrococcus in question *M. Pasteuri*—a name that has not been generally accepted, and for which I now propose to substitute the name placed at the head of this paper, *M. pneumoniæ crouposæ*. In my paper last referred to, which was read before the Pathological Society of Philadelphia in April, 1885, and published in *The American Journal of the Medical Sciences* for July of the same year, I say: "It seems extremely probable that this micrococcus is concerned in the etiology of croupous pneumonia . . . . but this cannot be considered as definitely settled by the experiments which have thus far been made upon the lower animals."

Fraenkel's first paper[2] relating to the presence of this micrococcus in pneumonic exudate was published shortly after my paper last referred to.

Since the date last mentioned the extended researches of Fraenkel,[3] Weichselbaum,[4] Netter,[5] Gamaléia,[6] G. and F. Klemperer,[7] and others, have established the fact that this micrococcus is the usual cause of croupous pneumonia.

Recognizing this, we propose hereafter to designate it *Micrococcus pneumoniæ crouposæ*. This corresponds with the nomenclature adopted by Flügge in describing other pathogenic bacteria—*e. g.*, *M. gonorrhœæ*, *B. typhi abdominalis*, *Spirillum choleræ Asiaticæ*.

The name "diplococcus pneumoniæ," which has been adopted by most German bacteriologists, and following them by many English and American authors, is objectionable because this coccus is not truly a diplococcus, although commonly seen in pairs in preparations made from pneumonic exudate, or from the blood of an infected rabbit. But it is also frequently seen in short chains of three or four elements, and in cultures upon nutrient agar it often forms long chains. It is, therefore, more properly called a streptococcus. Gamaléia calls it *Streptococcus lanceolatus Pasteuri*. We prefer, however, the more general generic name, "micrococcus," and do not consider it necessary that the name should be descriptive of the mode of grouping of the cocci.

It may be questioned whether "diplococcus," as a generic name, is entitled to a place in our nomenclature. It simply represents a form of association that is common to all micrococci, although more persistent in some than in others, and which results from their multiplication by binary division. Now, some of the so-called diplococci multiply in one direction only, forming pairs, and longer or shorter chains, as in the case of the micrococcus under consideration; while others multiply in two directions, forming pairs and, by transverse division, groups of four—*e. g.*, *Diplococcus citreus conglomeratus* (Bumm), *Diplococcus roseus* (Bumm). Thus a most important generic character—division in one or in two directions—is ignored by those bacteriologists that use the term diplococcus as a generic appellation.

Again, some of the micrococci commonly described under the generic name "streptococcus" are seen, under certain circumstances, only, or chiefly, associated in pairs.

We object, then, to the use of the term "diplococcus," as a generic name for microörganisms of this class, as being unscientific and misleading.

CLINICAL MEMORANDA.

A CASE OF HYDROGEN DISULPHIDE IN THE URINE.

By LOUIS KOLIPINSKI, M.D.,
of Washington, D. C.

A retired gentleman of sixty-seven, strongly addicted to alcohol, which had seriously undermined his robust constitution, had been treated for chronic gastritis, the result of the long-continued use of intoxicants. He had recovered sufficiently to digest bland food, when a return to his old habits soon caused a relapse. He developed insomnia, mental hebetude, and impairment of memory to such a degree that on one occasion, whilst about in the city, he was unable to find his way home. There had long been feebleness and unsteadiness in walking and complaint of shooting pains in the lower limbs, which, with a decided atrophy of their muscles, were ascribed to chronic alcoholic neuritis. His wife had noticed a slight evening fever, which at first could not be confirmed. There was complete anorexia, and with this there was an intermittent desire for strong drink. His feebleness confined him to bed, and apathy made him converse but little. Profuse nightly incontinence of urine alternated with a frequent desire to urinate by day. The prostate was moderately enlarged, but further urethral and vesical exploration was omitted, because of the man's general condition.

My attention had been called to the strong, peculiar odor of the urine before the symptoms of vesical disturbance began. On examination I found, June 5, 1891, the urine of a red color; acid reaction; slightly turbid; without sediment; specific gravity 1018; no albumin, bile, or sugar. By lead-acetate paper, H_2S was found to be present. A few epithelial cells were found.

For one month—during which time the patient improved so much that he was able to leave his bed, digest food, and take a renewed interest in the things of every-day life—the urine continued of the same composition. It was frequently examined, and with strict precaution as to its freshness, and the continuous presence of H_2S was uniformly detected. The question to be solved was, Where and how did the H_2S originate? The most plausible theory of intestinal decomposition and absorption was entertained and rejected, the evacuations being fairly regular and healthy. The speculation that its origin was from preëxisting cystin could not be proved by finding the latter, and finally the otherwise normal character of the urine excluded the assumption that it was a product of abnormal substances like albumin or pus. The books at hand helped me to no clue.

At the end of a month the patient's condition again grew worse. His bad symptoms were intensified, nocturnal fever returned, and the urinary incontinence grew annoying. A persistent hiccough gave the patient no rest. There now appeared a new light to clear up the mystery of the H_2S. The patient began to complain of pains about the anus at the site of a former ischio-rectal abscess. There was found on the right side around a small, circular cicatrix a moderate area of induration, extending forward to the scrotal fold, slightly tender and fluctuating. A free incision gave exit to about an ounce of pus having a strong odor of H_2S. The abscess was thoroughly washed out and left clean and dry. The hiccough had now continued for twenty-four hours.

The night of this day (July 4th) the patient was comatose, with a rising axillary temperature of 104° F.; the pulse was 140, the respiration 44. The hiccough was still present. The skin was burning hot; the body entirely relaxed; the soles of the feet responded to irritation. The bladder was emptied by catheterization twelve hours after the abscess had been opened, and the urine thus collected was found to present these characteristics: color red; acid reaction; specific gravity 1019; slightly turbid; opaque sediment; H_2S present; a trace of albumin; indican in excess; granular epithelium, and blood-corpuscles.

With the removal of the catheter the hiccough, continuous for over forty-eight hours, ceased. The status of the case was sufficiently desperate to justify a fatal prognosis. The man was, however, treated with repeated enemata of caffeine and antipyrin (total, twelve grains of caffeine and thirty grains of antipyrin). In a few hours he showed slight symptoms of improvement, the temperature becoming stationary and then declining, so that at 4 A.M. he was conscious. The next day the thermometer did not rise above normal. The patient conversed with his family, recognizing each and saluting them individually, but at intervals became lost in a mild delirium. There were persistent efforts to eject mucus from the throat. He took fluid nourishment readily. Toward noon and again toward evening he vomited large quantities of altered blood. On the following day diarrhea set in; the stools were offensive and contained undigested material, showing the existence of gastro-intestinal indigestion. Bismuth and opium stopped the discharge. The urine contained an excess of indican, but was otherwise normal. H_2S was not again found in it. The delirium was worse at night. The man at times complained of abdominal pains, and the inguinal and hypogastric regions were slightly tender; the respiratory and heart sounds were normal; the skin was not jaundiced; the face had an ashy hue, with darker pigmentation of the eyelids. There was occasional hiccough. The fever now returned and the patient grew drowsy and soon could be aroused only with difficulty. Incontinence of urine became complete.

On the 13th of July he was unconscious, the temperature at its maximum being 103° F. The body was bathed in profuse sweats; the left half felt cooler than the right, and lay as in cerebral hemiplegia, but there was no paralysis. This state became intensified, and the patient expired quietly on the 15th.

The symptoms as narrated, and as they successively presented themselves, added additional interest to the case. The intense febrile reaction, the apparent improvement and the fatal return of the typhoid symptoms made the diagnosis obscure.

The autopsy, which was confined to the abdominal cavity, showed a dilated stomach, its mucous membrane, as well as that of the small intestine, containing spots and patches of extravasated blood. The kidneys were cirrhotic, the right containing several small cysts and calcareous infarctions. The liver was in a state of fatty degeneration, but not markedly diminished in size; there was little evidence of cirrhosis. The spleen was dark and friable and not enlarged. In the gall-bladder was a little pale bile and two small calculi. The skin was of a natural color, and there was no fluid in the abdominal cavity. The ischio-rectal abscess was thoroughly explored and found empty and granulating. The bladder was contracted, and there was no induration or inflammation in its neighborhood. It appears, then, that acholia was the cause of death. The absence of icterus was a singular feature.

The urine in this case was especially instructive. Standard works furnish scant information on this subject, or none at all. This is particularly true of works on urinary analysis. Here was an old ischio-rectal abscess (the residual variety of Pajet), for a long time manifesting itself only by the presence of a decomposition-product in a natural secretion.

PERFORATING WOUND OF THE RIGHT LUNG; RECOVERY.

BY GEORGE EVANS READING, M.D.,
OF WOODBURY, N. J.

ON October 2d, in my absence, an urgent message was left at my office, to come at once and see R. E. G., who, it was stated, "was dying." I had, on previous occasions, attended the man for severe attacks of intestinal colic, and jumped to the conclusion that the present trouble was of a similar nature.

On reaching his home, three miles out of the city, I found that the man was suffering from injuries caused by the horns of a vicious bull that had attacked him, tossing and goring him several times. The man was seated in an easy chair, in a condition of decided shock, the surface of the skin covered with a clammy sweat, and the pulse almost imperceptible at the wrist. The respiration was rapid and shallow. Any attempt to assume the recumbent posture brought on an attack of suffocation.

I immediately administered a hypodermatic injection of morphine sulphate, gr. ¼, with atropine sulphate, gr. $\frac{1}{100}$. Respiration and circulation soon improved.

Put to bed and examined, it was found that the body was covered with scratches and bruises; on the right side of the thorax was a wound three inches long, the center of which was two and a half inches below the right nipple. Through this wound, air was expelled with each expiratory act, but little or none entering during inspiration. The wound had evidently been bleeding profusely, as the patient's clothing was saturated with blood.

The skin and superficial fascia were torn from the ribs for some distance above and at each extremity of the external wound; in the fourth interspace, almost exactly beneath the right nipple, was an opening through which the air was escaping. The wound in the intercostal muscles was three-fourths of an inch in diameter; it evidently communicated with one or more of the larger bronchi, as there was a free passage of air through it during both inspiration and expiration, when the overlying tissues were held up; but when these tissues were undisturbed they acted as a valve and prevented the entrance of air during inspiration. There was a slight prolapse of lung-tissue into the wound in the intercostal muscles, but, as the tissue did not project beyond the outer surface of the ribs, it was deemed best to leave it undisturbed. There was no evidence of hemorrhage into the pleural cavity.

The wound was thoroughly irrigated with a hot one-to-one-thousand solution of corrosive sublimate. A firm, thick pad was placed over the wound in the lung. A bundle of No. 8 iron-dyed silk was laid at the bottom of the external wound, to afford drainage, and the wound was closed by means of interrupted silk sutures. The area of the injury was covered with a pad wrung out of a one-to-two-thousand solution of mercuric chloride; this, in turn, was covered with a dry pad extending some distance in every direction beyond the periphery of the former, and the whole dressing secured by a wide bandage applied around the chest and over the shoulder in such a way as to limit as much as possible the movement of the ribs on the injured side.

At the end of an hour, as the patient still presented symptoms of shock, the hypodermatic injection of morphine and atropine was repeated, and alcoholic stimulants were ordered. At 3 P.M.—eight hours after the accident—the patient had not yet fully reacted; the temperature was 97.5°, and the pulse was 60. By 10 P.M. reaction was fully established, and the temperature had reached 99.5°. The temperature reached 100.5° at three o'clock the next afternoon, but by 10 P.M. it had receded to 99.5°, and it never again reached 100°. It remained in the neighborhood of 99.5° for four days, when it became normal in the morning; three days later—one week after the injury was received—the evening temperature was also normal.

The first dressing was not disturbed for one week. Upon its removal it was found that the wound had united by first intention, except at the posterior angle, which was kept open by the silk strands used for drainage. These were now removed, and the wound washed out with a one-to-two-thousand bichloride solution, and the dressings were re-applied. This dressing was also left in position for one week; upon its removal the wound was found to have healed solidly throughout, and the sutures were removed.

Not one drop of pus formed during the whole course of treatment; the total amount of drainage was only sufficient to soak through two layers of Canton flannel (of which the pads were composed, no better material having been at hand), over an area five inches long by two inches in width.

Convalescence was uneventful, except for an attack of intermittent fever that developed four weeks after the injury was sustained. This yielded readily to quinine and arsenic. Ten weeks after the injury was received, the man was attending to his usual duties.

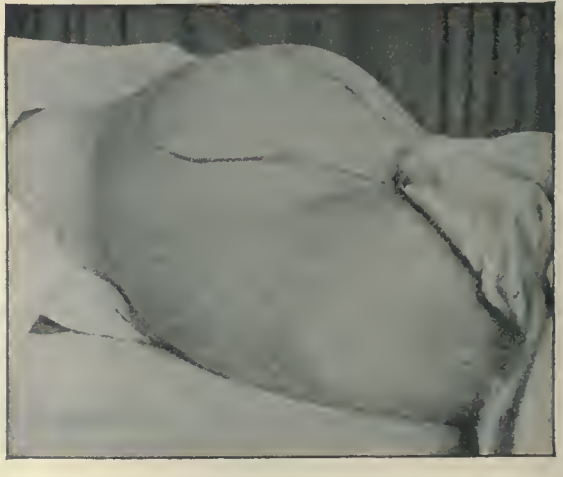
REMARKS.—The fortunate issue in this case was largely due to the fact that the wound was of such a nature that the skin and superficial fascia could be used as a valve to close the opening in the lung, so that the task of rendering the wound aseptic was an easy one, so far at least as direct contamination was concerned. The fact of the patient being in the pure air of the country was an important factor in the result, as thus the risk of septic inoculation of the wound by the way of the air-passages was reduced to a minimum. The small amount of blood that escaped into the pleural cavity also had an important bearing upon the result, for with a large hematoma of the pleura the patient would have had a greatly diminished chance of recovery.

179 SOUTH BROAD STREET.

TYMPANITES AND PREGNANCY.

BY BARTON COOKE HIRST, M.D.,
OF PHILADELPHIA.

ONE will find in almost all text-books on obstetrics the rules for differentiating tympanites from pregnancy, Winckel's book being a notable exception; but nothing is said about the coëxistence of the two, although the diagnosis may be much obscured if the abdominal



cavity is greatly distended by flatulence and at the same time contains a pregnant womb. While demonstrating abdominal palpation to a small class, the individual represented in the photograph was brought before me. On first palpating the abdomen, it occurred to me that the woman was not pregnant at all, as I could feel nothing

distinctive, and percussion yielded a tympanitic note all the way down the median line to the symphysis. On more careful palpation, however, a tumor was distinguished on the right side of the abdominal cavity corresponding in size and shape to the gravid womb near term. On auscultation, the fetal heart-sounds were heard far to the right. On percussion, there was an area of dulness (marked on the photograph) which, it may be observed, was confined entirely to the right side. The abdominal walls were so tense that it was quite impossible to feel any characteristic parts of the fetus. As may be seen in the photograph, the distention of the abdomen is perfectly symmetrical. The presence of the pregnant uterus is masked on account of the greater distention by the inflated intestines. On careful percussion and palpation, it could be demonstrated that coils of intestines overlapped the uterus on the left, so that the area of dulness did not represent the true width of the uterus. I have seen the intestines in front of the womb in only one other case, in which the girl had laced so tightly that the uterus at the sixth month was reduced to about four inches or less in breadth, but was lengthened almost to the liver, the upper part above the umbilicus being covered by intestines.

By the coëxistence of tympanites and pregnancy, the abdomen (as can be seen in the illustration) is naturally very much enlarged, presenting the following measurements:

Circumference	117 cm.
Symphysis to umbilicus . .	21 "
Umbilicus to ensiform cartilage .	23 "

It would be very easy to overlook pregnancy in such a case, especially before the sixth month, when the uterine tumor would scarcely be appreciable by palpation, except under ether and with deep pressure, and even so might be indistinguishable. Indeed, I understand that this woman had applied for admission to the Philadelphia Hospital some months before, and had been turned away, as she was declared to be not pregnant.

NEW INSTRUMENTS.

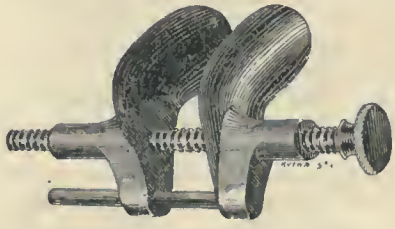
A NEW NASAL SPECULUM.

BY H. N. SPENCER, A.M., M.D.,
PROFESSOR OF DISEASES OF THE EAR IN THE MISSOURI MEDICAL COLLEGE AND ST. LOUIS POST-GRADUATE SCHOOL OF MEDICINE.

IN the present state of otological practice a nasal speculum is quite as much a necessity as an aural speculum.

For mere inspection and for much practical work, I have found the conical form, a modification of the aural speculum, to answer a good purpose. I described this instrument in 1879 in an article on the "Mechanics of Naso-pharyngeal Practice."[1] There are instances, however, especially in operative procedures, in which this does not fulfil all of the requirements, the dilatation being necessarily limited. The objections to the specula at our command—Thudichum's, Fränkel's, Duplay's, etc.—are generally so well understood that it is unnecessary to recite them. The instrument presented herewith has grown out of my own necessities, and I submit it for the consideration of others.

As represented in the cut, the two blades travel on a right and left thread-screw. One-half the length of the screw has a right-hand and the other a left-hand thread. There are twenty-four threads to the inch, and pitched in opposite directions: it is evident that every complete revolution of the screw will separate the blades one-twelfth of an inch. If a more rapid operation of the blades should be desired, a screw of greater pitch would effect it. The blades are so adjusted on the screw that they will come together where the right- and left-hand threads meet. This relative position is constantly maintained by means of the small guide-rod that appears in the cut running parallel with the screw. One end of the guide-rod is made fast in the lug of the blade nearer the knob-end of the screw. The other end travels freely through the lug of the opposite blade.



The threaded portion of the instrument is made quite long to insure easy working and to resist the twisting strain to which the blades are subjected. This, also, is a precaution against wear. The screw is made of hard steel, which contributes further to strength and durability. The mould of the outer aspect of the blades, slightly flaring at the extremity, makes the instrument self-retaining.

The instrument when in position rests upon the upper lip. In patients with mustaches, I have found a still further advantage to accrue from placing the screw and guide-rod below the blades. The mustache is thus held out of the way, in this way often sparing annoyance to the operator.

[1] St. Louis Courier of Medicine, July, 1879.

MEDICAL PROGRESS.

The Causes of Failure to Abort Syphilis by Excision of the Initial Lesion.—Excision of the chancre in the hope of aborting syphilis is an old procedure that has at times been quite extensively practised. It has, however, never gained a permanent foothold; of a total of about 460 cases on record, in only 106 have successful results been claimed. By far the larger number of syphilographers of to-day are opposed to the practice, but among the minority who still adhere to it is the learned syphilographer of Paris, JULLIEN, who, in a recent article based upon an extensive experience, says: "I believe in the possibility of interrupting or attenuating the course of syphilis at the time of the initial sclerosis; we should not fold our arms during the period in which a patient's existence is to be decided, or think that all is lost before anything has been commenced."

TAYLOR (*Medical Record*, 1891, No. 1078) has reported a series of cases illustrative of the inutility of

excision of the chancre. In one case, a minute papule was first observed twenty days after the patient had indulged in sexual intercourse with a syphilitic. The sore was touched with pure nitric acid, and the greatest care was exercised to secure thorough removal of the lesion without contaminating the adjacent healthy tissues. The wound healed kindly; yet, notwithstanding the precautions that had been taken, the inguinal ganglia were typically enlarged thirty days after operation, and twelve days later general syphilitic manifestations appeared. In the second case, a minute fissure appeared on the dorsum of the penis seventeen days after sexual intercourse with a syphilitic. A piece of skin including the fissure, measuring half an inch by three-quarters of an inch, was excised. Healing was uninterrupted, and the scar showed no induration; but, twenty days after the operation, there was well-marked inguinal adenopathy, and, subsequently, the usual secondary manifestations appeared. In the third case, an examination preliminary to the performance of circumcision revealed the presence, on the free border of the prepuce, of a small, brownish-red, not excoriated papule, about the size of the head of a small tack, which had appeared on the preceding day, two weeks after sexual intercourse. The operation was performed four days later. At this time there was no perceptible enlargement of the inguinal ganglia. As the prepuce was quite redundant, fully an inch and a half of tissue was removed; healing was prompt, without induration of the cicatrix. Thirteen days after the operation, inguinal adenopathy was quite evident. Thirty-two days later a typical roseola appeared; shortly before this, minute hard cords could be detected on the dorsum of the penis. On microscopic examination of the excised portion of the prepuce, there was found at the site of the initial lesion a small, superficial, and sharply-circumscribed ulcer, surrounded by almost normal skin, except that the peri-vascular spaces were distended with small round cells, and the endothelial cells lining the arteries and veins were swollen, and appeared to be proliferating. This cell-investment extended a considerable distance beyond the ulcer. This condition of the bloodvessels seems to show that when the primary sore is quite small and of only a few days' duration, syphilis is deeply rooted and, in all probability, has involved the vessels even before the appearance of the sore.

For comparative purposes, microscopic examination was made of a prepuce upon the lower part of which, near the frenum, was a typical hard chancre of ten days' duration. It was found that at a distance of fully an inch and a half from the chancre, the cell-changes around the vessels were very decided, the cells being in process of active proliferation. As an instance of the great rapidity of the syphilitic infection, reference is made to the now classical case reported by Berkeley-Hill, in which thorough cauterization of a lacerated frenum, within twelve hours after coitus, proved powerless to prevent the development of syphilis. As a further confirmation of the view that the process of infection in syphilis is from the beginning one of constant growth and diffusion, reference is made to the observations of Küleneff on the so-called lymphatic cord of syphilis. The cords were excised from the dorsum and sides of the penis in five cases, in which the chancres were of from a fortnight's to two months' duration. These cords were found to be dependent upon syphilitic endo-phlebitis and peri-phlebitis, the morbid process commencing primarily in the wall of the vein, probably in the inner coat. The tendency of the cell-infiltration to pass into young connective-tissue elements seems to indicate that the nature of the morbid process is identical with that of the initial syphilitic sclerosis; and, according to Küleneff, the development of this cord should be regarded as an early manifestation of vascular lesions in syphilitic patients.

In view of the facts, it seems probable that, contrary to the views heretofore held, in the first period of incubation, the infectious agent of syphilis is being rapidly diffused, instead of, as formerly supposed, smouldering in a cold and aphlegmasic manner in a sharply-limited area.

The Therapeutic Applications of Hydrogen Dioxide.—Richardson (*Asclepiad*, 1891, viii, 32) gives a number of formulæ containing hydrogen dioxide, together with the indications for their employment. Each dose contains a little more than three drams of ten-volume hydrogen dioxide and a dram or two of pure glycerin and is made up to an ounce by the addition of distilled water. The dose should always be well diluted. For the colliquative sweating of pulmonary tuberculosis, fifteen minims of dilute sulphuric acid are added. When a tonic is desired, as in the course of influenza, a grain of quinine, with three or four minims of dilute hydrochloric acid, are added; if an anti-periodic is desired, five grains of quinine may be added. For hemoptysis and analogous forms of hemorrhage, fifteen grains of tannic acid, with or without sulphuric acid, may be added. In case of cough, preventing sleep, as in chronic and asthenic bronchitis and in pulmonary tuberculosis, an eighth or a quarter of a grain of morphine sulphate from three to five minims of dilute hydrochloric acid, and a dram of syrup of tolu are well added. In diabetes, it is useful to add a quarter or an eighth of a grain of codeine, a small proportion of a mineral acid, and a dram of alcohol. In cases of asthenia and anemia, the addition of ten minims of dilute phosphoric acid and of a grain or two of iron pyrophosphate, with the addition of from five to ten minims of tincture of digitalis, if the action of the heart is rapid and feeble, will prove serviceable. When indicated, ten minims of dilute phosphoric acid, a grain of quinine, and a grain or two of iron pyrophosphate may be added to the dose; a dram of alcohol and a thirty-second of strychnine may be additionally conjoined. The mere addition of half an ounce of alcohol makes a combination that may be usefully employed as an anti-spasmodic or as a menstruum for the administration of other substances that are soluble in alcohol and do not readily undergo decomposition in the presence of oxygen. Three or four minims of amyl nitrite may yet be profitably added. A dram of ozonic ether may sometimes be advantageously substituted for the hydrogen dioxide. Thirty minims of ozonic ether and a dram of syrup of tolu in glycerin and water are most effective in pertussis. The addition of a minim of creasote to the dose of hydrogen dioxide makes a useful antiseptic, deodorant, and anti-spasmodic, especially in fermentative dis-

orders of the stomach. For salivation, five minims of the solution of potassium arsenite may be added to the usual dose of hydrogen dioxide.

A gargle may be made of—

Tannic acid . . .	10 grains.
Pure glycerin . . .	1 ounce.
Alcohol	4 fluiddrams.
Distilled water . . .	4 fluidounces.
Solution of hydrogen dioxide (10 vol.) sufficient to make . .	8 fluidounces.

A useful collyrium may be prepared by combining:

Solution of hydrogen dioxide (10 vol.) . .	4 fluiddrams.
Pure tannic acid . .	5 grains.
Rose-water sufficient to make	8 fluidounces.

An evaporating lotion may be made of—

Alcohol	4 fluidounces.
Anhydrous ether . .	1 fluidounce.
Distilled water . .	4 fluidounces.
Solution of hydrogen dioxide (10 vol.) sufficient to make . . .	12 fluidounces.

For inunction of the skin in cases in which desquamation occurs, as in scarlatina, an ointment may be prepared by rubbing up ozonic ether with spermaceti ointment, so as to form a thin paste; this may, if desired, be rendered thick by the addition of more spermaceti, or thin by the addition of olive oil.

Dissecting Aneurism of the Ascending Aorta in Association with Chronic Nephritis; Rupture into the Pericardium.—At a meeting of the Berlin Society for Internal Medicine, TROJE (*Deutsche medicin. Wochenschr.*, 1891, No. 46, p. 1271) presented the specimens obtained from a woman fifty-six years of age who, four years previously, was seized with apoplectic symptoms from which she recovered. Three years later, the patient developed uremic coma in conjunction with symptoms of chronic nephritis, and was successfully treated. Some nine months before death, she again came under observation on account of increased dyspnea, sleeplessness, and edema. The physical signs indicated the existence of aortic incompetence and moderate hypertrophy of the heart. There existed, in addition, the symptoms of a chronic, diffuse nephritis. The radial arteries were tense and tortuous. The urine was subnormal in quantity and contained considerable albumin. There was also albuminuric retinitis. Death took place during a uremic attack attended with convulsions. At the autopsy, in addition to the evidences of cardiac hypertrophy and aortic insufficiency, an oblique rupture of the internal and middle coats of the aorta a short distance above the semilunar valves was found. Through the rupture a large volume of blood had found its way beneath the pericardium covering the great vessels and into the pericardial cavity, entirely enveloping the heart. The aorta was slightly thinned and dilated at the seat of rupture, but otherwise normal, although atheromatous beyond and behind. The coronary vessels were also atheromatous. The kidneys were contracted and contained cysts; the capsules were adherent; the surface of the organs was irregular; the cortex was diminished. The occurrence of dilatation, thinning, and rupture is made dependent upon the impact of the current of blood projected by an hypertrophied heart under conditions of increased arterial tension.

Puerperal Eclampsia.—In addition to seven cases previously reported, HERMAN (*Transactions of the Obstetrical Society of London*, 1891, xxxiii, 3, p. 315) reports five more cases of puerperal eclampsia, in which special attention was directed to observations of the temperature and of the urine. Four mothers died; eight recovered. Six living children were born; four died *in utero*; one was not viable; one patient died undelivered. There was no evident relation between the paroxysms and the temperature. The quantity of urine was diminished in all but two of the cases observed from the beginning of the disease. Of the two exceptional cases, one died; in the other, evidences of renal disease persisted after childbed. In all of the cases, the excretion of nitrogenous matter in the urine was absolutely diminished, and in most the percentage as well was diminished. At some time in all, the urine contained albumin in large quantity. In three, the proportion of albumin appeared to be increased in consequence of the paroxysms. Two cases in which the precipitate of albumin contained the largest proportion of paraglobulin recovered. Of three cases in which the proportion of paraglobulin was smaller than in the rest, two died; while in two the evidences of renal disease persisted. In all of the cases that recovered, there was rapid increase in the quantity of urine and in the proportion of contained nitrogenous matter and a diminution in the proportion of albumin. This restoration did not, as a rule, take place until some hours after the cessation of the attacks, and in the cases in which cessation of attacks preceded delivery, progressed more rapidly after delivery. This restoration of renal function failed to take place in the cases that died. Retinitis was present in only two cases, both of which terminated fatally.

Potassium Cantharidinate in the Treatment of Pulmonary Tuberculosis.—After the tentative employment of subcutaneous injections of potassium cantharidinate in sixteen cases of pulmonary tuberculosis in various stages of the disease, FENWICK and WELSFORD (*British Medical Journal*, No. 1617, p. 1349) conclude that the remedy is absolutely useless to produce any obvious beneficial effect. In moderate doses it is likely to give rise to albuminuria, or even hematuria, with strangury and pain in the loins.

Fatal Poisoning by Magnesium Sulphate.—SANG (*Lancet*, No. 3558, p. 1037) has reported the case of a woman, aged thirty-five years, that shortly after taking four ounces of magnesium sulphate dissolved in hot water, was seized with burning pain in the stomach and bowels, with difficulty of breathing and a sense of weakness in the extremities. The mucous membrane of the tongue and mouth was intact. There was neither nausea nor vomiting nor purging. Collapse set in and the patient died comatose. Death was ascribed to a direct action upon the cerebro-spinal system.

The Antiseptic Treatment of Burns.—In the treatment of burns, especially those that exceed the second degree, MAYLARD (*Glasgow Medical Journal*, 1892, xxxvii, 1) recommends that such clothing as can be conveniently removed be taken off; if adherent, it should be cut away. The wound is washed with a warm 1 : 2000 solution of mercuric chloride; then covered with perforated protective (oiled silk) that has been steeped in the mercuric solution; over this is placed a layer of borated lint wrung out of mercuric solution; finally, a covering of gutta-percha tissue is applied. The dressing is enveloped in sublimated "Gamgee" tissue and secured by means of a bandage. The dressing is to be renewed as soon as it becomes saturated with secretion. The protective may sometimes be omitted. The advantages claimed for this method of treatment are that the parts sterilized by the burn are kept sterile; inflammation is subdued and tissue-destruction prevented; discharge is diminished; dressings are infrequent and attended with little or no pain; there is an absence of offensive odor; necrotic tissue is rapidly thrown off by healthy granulations; the resulting cicatrix is the smallest possible; constitutional symptoms are reduced to a minimum.

A Swallowed Plate of False Teeth Passed by the Bowel.—ROSENZWEIG (*British Medical Journal*, No. 1614, p. 1204) has reported the case of a man who was awakened from an after-dinner nap by a sense of suffocation and pain in the throat, while a plate of false teeth that he had worn was missing. The throat was red and irritable, but no laceration or hemorrhage was detected. Solids and liquids could be swallowed freely and without pain. A sponge-probang passed readily into the stomach. The patient was directed to go to bed and to adopt a restricted diet. For three or four days there was considerable hypogastric pain, with alternate diarrhea and constipation. At the end of three weeks the patient would no longer remain in bed, and resumed his ordinary diet. Seven weeks subsequently to the accident, some time after a long drive, he was seized with severe abdominal pain, and after considerable difficulty and manual assistance the plate of teeth was passed *per anum*. The teeth were attached to a gold plate, the whole measuring 2¼ inches in its longest diameter, 1¼ inches in its shortest diameter, and ¾ of an inch in its greatest thickness.

Visceral Hemorrhages in Stillborn Children.—In an exhaustive paper, SPENCER (*Transactions of the Obstetrical Society of London*, 1891, xxxiii, 3, p. 203) presents an analysis of the findings in one hundred and thirty autopsies in children stillborn or dying shortly after birth. He found congestion or edema and hemorrhages in various viscera the rule. Hemorrhages were present in cases delivered naturally or by version or by forceps, through normal and abnormal pelves; in primiparæ and in multiparæ; with large and with small children; in easy and in difficult, and in rapid and in protracted labors. Hemorrhage was most common and most profound in children subjected to pressure in the birth-canal, or by instruments or by the hand of the attendant, especially when delivery was effected by a lower extremity. Cerebral hemorrhage was more frequently found in stillborn children delivered by the forceps than in those born by the breech, and in those delivered by the breech than in those born naturally by the head. Hemorrhage into other viscera was more common in labors in which the presentation was pelvic than in those in which the presentation was cephalic. The hemorrhage and the accompanying injury were, in many cases, the cause of stillbirth; when not immediately fatal, they were attended with the gravest consequences. The accident is to be avoided by preventing premature rupture of the membranes; by artificial dilatation of the birth-canal, when necessary; by restricting the employment of version and other artificial manipulations to urgent cases; and by preferring cephalic to podalic version in suitable cases. The employment of the forceps should be absolutely limited to cases in which there exists some pressing danger to mother or child; the forceps should never be employed merely to shorten the time of labor. In breech-presentation, examination of the genital organs of the child should be sedulously avoided during delivery. As soon as the lower extremities are born they should be wrapped in antiseptic wool (which keeps the child warm, prevents the grasping hand from slipping, and protects the parts from pressure). If traction be necessary, it should be made over wool wrapped around the child's limbs or pelvis; it should never be made by the hand surrounding the child's waist. In delivering the after-coming head, care should be taken that the sterno-mastoid muscles are not unduly stretched or compressed. When the after-coming head is in the pelvis, and there is even slight difficulty, the forceps should be resorted to.

Post-paludal Pneumonia.—HADJI-COSTA (*Revue de Médecine*, No. 11, 1891, p. 927) has recorded ten cases of pneumonia in individuals presenting a history of malarial infection. His observations lead him to believe that chronic impaludism predisposes to the development of a pneumonia characterized by a special train of symptoms. The invasion is usually insidious. The classical symptoms of a frank pneumonia, such as dyspnea and pain in the side, are mild or wanting. In addition to the chronic congestion of the miasmatic affection, organic and functional derangements of the abdominal organs are common. Nervous and adynamic symptoms predominate. Resolution is often delayed. Suppuration may ensue. The mortality is high. Treatment by means of quinine and alcohol exercises a most favorable influence upon the course of the disease.

Hemorrhagic Purpura, with a Tumor of the Thymus Gland.—NASON (*British Medical Journal*, No. 1617, p. 1352) has reported the case of an adult male who presented epistaxis, hematuria, and a purpuric eruption; death took place in coma. At the autopsy, in addition to extravasations of blood in many superficial and deep structures, a large extravasation was found occupying the right frontal lobe of the cerebrum. Numerous small hemorrhages were found in other parts of the brain. In the upper portion of the mediastinum was found a large lympho-sarcoma occupying the site of the thymus gland. A possible relation is suggested between the lymphoid cells supplied to the circulation by the thymic tissue and the development of purpura.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

DUTIES OF THE YOUNG PRACTITIONER.

THE young practitioner, settling in the larger towns and in cities, first of all desires to secure a practice; he wishes, so soon as possible, professional success. How shall he attain it in the best and most enduring form? Let us leave out of consideration practice in the country, where the aspects of the problem are somewhat *sui generis*, and let us also suppose that the young physician has been properly educated, and has an adequate intellectual equipment for his calling. It also goes without saying that, though perhaps a little slow in coming, success will more certainly come to the gentleman—the man who is respectful, self-respecting, well-bred—than to one not a gentleman. The commonest patient at once recognizes the boor turned doctor, while the most vulgar reverence gentle strength in their physician, and therefore give him confidence—and calls.

But to himself, his colleagues, and associates, and to his profession, what are some of the chief duties of the young practitioner?

First and foremost, that he make haste slowly; that he be content to wait. Many, even most of the present professional evils that bring disgrace upon physicians and their calling are due to the feverish desire for quick success. Policy aside, it is one of the duties and glories of our work to administer rebuke to the world, the rule of which is *Success at any cost*, by duty quietly done and self-renunciation habitually performed in the interest of humanity and of dignity. The desire to get on, the need of money, the wish to reap reward for the long years of study and hope deferred, are powerful motives, and must be allowed their legitimate and proper sway. It is hard to act upon the evident truisms that the best fruits ripen slowly; that deserving somehow and almost always gets its desert; that slow success is usually far better than quick success. The last point is especially true in view of the fact that the young physician should have much leisure for needed study, for filling the blanks in his knowledge, for thoroughly examining and deepening his comprehension of every case of disease that comes under his care.

Too much haste, for example, leads him to adopt the vile methods of advertising that have often besmirched honor and blocked the way to enduring and deserved success. Let him beware of the daily paper and of the reporters. These gentlemen detect at a glance whether one wishes sneakingly to advertise or not. If one determinedly and absolutely refuses them the privilege of using his name about professional opinions, his surgical operations and cures, they dare not disobey. We all know that the physicians whose surgery and skill are heralded in the penny press, are so advertised by their own will and doing, and quite as well do we know that the act and fact, however much money it brings, brings also dishonor and the contempt of one's professional fellows. It is poor policy in the long run.

The young physician in a city will probably seek connection with the out-patient department of some hospital or dispensary. But, for Heaven's sake, don't let him start a new institution of this kind! We are developing a genuine hospitalomania. The need of hospitals was at one time so great that, satisfaction long since attained, the historic momentum goes on with blind fury to self-destruction. The desire of the young practitioner for patients and experience drives him into this field—the abuse of which is his own professional suicide. If the older visiting physicians will not coöperate to limit the abuse, let him seek to do it himself. The way out is not to treat the poor out-patient hospital visitor brutally and ungently, and the well-to-do patients (at present a large and increasing proportion) with an assumed and interested politeness, teasing them

to the private office on shallow pretexts. There can be no doubt that the crowds of out-patients that now have to be treated in an hour or two leads to diagnostic and therapeutic negligence that does patient and doctor each an injury. The evil must and will be remedied. Better that it be remedied soon and spontaneously than when it becomes a public scandal. Let no treatment be given when there is a reasonable belief that the patient can pay a small fee outside.

It is of the utmost importance that the young practitioner do not make the mistake of consorting and consulting with quacks. When quackery, as in homeopathic practice, is semi-fashionable, and some medical hybrid, occupying a doubtful position, wishes to bolster himself by the help of a regular practitioner, it is a great temptation to the younger man to accept the bribe. But there is no surer way to damage reputation and block professional advancement. Despairing pessimists and their natural but unknown allies, the quacks, may declaim that medical ethics have gone to the dogs and all that, but it is not so. If medical ethics have "gone to seed," then it is because the process of going to seed is preliminary and necessary to planting, and it conforms to the enthusiasm and function of the young to plant the seed, not to intone dirges. The seed needs soil; a little medical market-gardening and manuring will bring a new crop. It is not true that medicine is a business or only a business. Those that say so are stock-brokers and politicians turned physicians, and showing the cloven hoof of their ancestry. They will some day find a rude awakening from the shallow dream.

A very helpful condition of success is a good outfit of instruments, chosen with care, and especially with the advice of some older physician.

Not less necessary is a good reference library of new and authoritative medical books. A most needed and noble foundation would be a charity-fund to supply deserving young graduates with cyclopedias and standard treatises that epitomize modern medical science and research. The consultation of such works would often illumine an obscure case, obviate accidents and mistakes, save life, and be a daily means of professional progress and success.

Two, three, or more standard representative medical journals should also be subscribed for. No physician should be without either *The Lancet* or *The British Medical Journal*, and of our own country's journals, *The New York Medical Journal* or *The Boston Medical and Surgical Journal*, etc., should be taken. An excellent plan is to form journal and magazine clubs whereby at a minimum of expense, a large number of weekly and monthly journals may be passed among the club members. But in choosing journals those should be rejected that by reading notices and "puffs" of proprietary preparations and nostrums show that they are the mere agents of advertisers; and those that by silence as to quackery and medical abuses prove that it is not medicine but the growth of their subscription-lists and the sale of books that are the concealed motives of editor and publisher.

Finally, it may be urged that the young practitioner should continuously seek the advice and even the tutelage of the wiser and more experienced, long-established practitioner. Cases will be encountered that will puzzle the mind of the young practitioner or will baffle his skill. The practice of frequent consultations is eminently wise and greatly to be advised. It is to the advantage both of the patient and of the physician. It leads to a surer progress in the young, encourages a very desirable, much-needed professional *esprit de corps*, and makes medical progress more steady and assured. A condition, however, is that consultation fees shall be lowered. It is neither just to the patient, nor wise as a part of professional policy, greatly to increase the expense of dual advice. There is no reason why a consultation fee should be double or treble the customary fee; rather should it be less. But in this we trench upon another aspect of the question—the duties of the elder to the younger practitioners—left for future consideration.

THE PAN-AMERICAN MEDICAL CONGRESS.

THE Pan-American Medical Congress that will assemble in Washington in the first week of September, 1893, will, in all respects, be an occurrence of extreme interest and importance to the medical profession of the United States, and of all the countries associated in the movement. It is fortunate that a period has been chosen that will in no way conflict with the meeting of the International Congress at Rome, in the same year. From the latest authentic information as to its exact date, the latter meeting will occur in the last week of September. This is, indeed, quite as early a date as would commend itself for a large meeting in Rome. It will enable those that desire to attend both of these congresses, and to visit the World's Fair at Chicago,

which promises to be of so much interest and importance, to do so without difficulty, whether they come to this country from Europe, or from one of the South American countries, or are members of the profession in the United States. For the physician and scientist we believe the World's Fair will be found to have more importance than any previous similar exhibition.

It is evidently in the interest of the Congress that it should be held in the City of Washington. Careful examination of the Meteorological Reports show that the first week of September is usually more cool and agreeable than later in that month. Experience has shown also, we believe, that large scientific meetings occurring in any city where a World's Fair is in operation lose much of their importance and success by being dwarfed in comparison with the great exhibition.

It seems to us of undoubted importance that the entire profession of the United States should cooperate in rendering this Congress as successful as possible. Our interest in the International Congress is, of course, genuine, but it is exclusively from a scientific standpoint. We confidently expect that when next the International Congress comes to this country it will achieve a success as brilliant as any it has yet attained; but the Pan-American Congress appeals to us not only from the scientific standpoint, but also because it holds out distinct prospects of the most important results following from closer relations of reciprocity between the various countries that will be represented in it. It is most desirable that closer relations shall be formed between the members of the medical profession throughout the entire American continent.

It is true that in the past a comparatively small number of students have come to our leading schools from the South American countries or from Canada. We believe this has been largely because the standard required in our schools and the facilities and equipment provided have not been such as to commend themselves in contrast with the schools of Europe and Great Britain. But, fortunately, just at this time it has been decided that a compulsory four years' course of medical study shall be required at a number of our leading schools, and important improvements also are being made in all the facilities for instruction. There can be little doubt that, if the Pan-American Medical Congress is made as great a success as it should be, all the great schools, from New York to Illinois, will derive valuable results in the form of steadily increasing numbers of desirable students from Canada and the South American countries.

THE CHARLATAN TURNS PHILANTHROPIST.

AN interesting but very old psychologic phenomenon consists in the desire of those suddenly obtaining undeserved power to be over-kind and unduly generous. The efforts of the *nouveaux riches* at alms-giving and public benefaction are generally comical and often farcical. It is the foible of the place-hunter elevated to unaccustomed office to endow his cronies with favors. When the subconsciousness of trickery and secret evil becomes so troublesome as to make the poor wretch incapable of sitting still on a chair, however ludicrous to others, there is no more natural method of settling accounts with the duped public than to graciously divide plunder with it. And while the poor democratic beast bellows, Hurrah! at the supposed generosity, the scamp laughs in his sleeve at his success in the triple scheme of extended advertising, popular applause, and conscience stifled by posing as a public benefactor.

It one day popped into the fancy of an erratic English magazine-writer and literary pyrotechnist that there was a chance to give his dear public "a new thrill," by the espousal of the cause of an Italian quack—one MATTEI—who, without any preliminary medical education or pathologic study, assured the world that he could cure carcinoma. MR. STEAD gave the "Count" the service of his dashing pen, and advertised him as splendidly as if all the other zodiacal constellations had been darkened in the heavens, leaving there only the single glory of Cancer. MR. STEAD now informs his readers that the Count offers to make over to charitable objects the net profits accruing from the sale of his "great remedies" in the English-speaking world. MR. STEAD *is to nominate the committee that will dispose of the money.*

From a Western religious paper we learn that, spurred by the very pertinent inquiry as to what he proposed to do for the gutter drunkard (who for good reasons could not pay him one hundred dollars for treatment), KEELEY answered with a proposition to buy the Washingtonian Home in Chicago (for the rehabilitation of drunkards) and carry on the institution according to his own methods.

Before accepting such propositions, the trustees

should read either FROUDE's instructive essay, *A Cagliostro of the Second Century*, the history of PERKINS's tractors, of "Actina," or of any one of a thousand similar "wonders and delusions of a day."

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 21, 1892.

DR. ALFRED L. LOOMIS, PRESIDENT, IN THE CHAIR.

THE CONTAGIOUSNESS OF TUBERCULOSIS: PROPHYLAXIS.

THE last stated meeting of the Academy of Medicine was devoted to a consideration of the contagiousness of tuberculosis, and of the methods that might be most reasonably urged and adopted by the medical profession with the object of limiting the spread of the disease.

DR. T. MITCHELL PRUDDEN opened the discussion with a paper on "The Elements of Contagion in Tuberculosis." He defined the word "contagion" as an "invasion and reproduction within the body of pathogenic microörganisms." It was not necessarily an invasion by *bacteria*, because other organisms may be the elements of contagion, as, for instance, in malaria. It was encouraging to note that the word "contagious" no longer refers to infinite possibilities in the unknown, for the contagium in an infectious disease is the particular pathogenic microörganism itself the advent of which in the body ushers in those reactions of the body-cells that we call the disease; and an infectious disease is *contagious* when, under the ordinary conditions of life, the contagium can be freed from the body of a diseased person, and be conveyed to the body of another in such a condition as to be able to reproduce the disease in this second individual. Hence the old distinction between contagion and infection has become impracticable and valueless, as it is now known that the communicability of an infectious disease is largely dependent upon the physical properties of the contagia, which determine the manner in which the contagia are spread from body to body, or from place to place. The common conception of a contagious disease is one that taints the atmosphere surrounding the patient, but this is now true of any of the ordinary diseases except the exanthemata. Thus, typhoid fever, diphtheria, and tuberculosis may be highly contagious, or slightly contagious, depending upon the care, or lack of care, taken in disposing of the exudates and discharges of the sick.

Dr. Prudden closed his paper with the remark that whatever public or private measures for the prevention of tuberculosis we decide are wise to adopt, they must be so conceived that education may go hand in hand with the law, and that for humanity's sake, those stricken with the disease must be made to know that the necessary measures of reform do not entail ostracism or isolation. We must, with much tact, and a large knowledge of the ways of the world outside of the laboratory, wisely and cautiously select the appropriate measures, not forgetting that death meanwhile holds carnival.

DR. EDWARD G. JANEWAY then discussed "The Necessity and Feasibility of Efforts to Prevent the Spread of Pulmonary Tuberculosis." He said that surgical literature, prior to the discovery of the tubercle-bacillus, shows that many intelligent observers had been forced to admit that the disease was at times spread from one person to another. To-day there are few that do not believe that the tubercle-bacillus is the cause of tuberculosis, and this belief necessarily brings with it a belief in the doctrine of the contagiousness of the disease. As an instance of the contagiousness of tuberculosis, he cited a case occurring in a family that had been free from such disease. A child, two months of age, was kissed by a visitor who was suffering at the time from pulmonary tuberculosis, with cavities in the lungs and bacilli in the sputum. The child became infected with tuberculosis of the mediastinal glands, pulmonary tuberculosis rapidly supervened, and death occurred two months later. Dr. Janeway thought that every physician could recall cases illustrating the contagious nature of the disease, yet few such cases were reported, partly, no doubt, on account of the attitude of mind of the observer, and partly from lack of time to investigate every detail bearing upon the etiology of the cases. He adduced statistics to show that the great majority of people having pulmonary tuberculosis were at an age when they were most apt to mingle with others, either while at work or at play. The statistics also showed the baneful influence of a concentration of population. Dr. Janeway looked forward with dread to the injurious effects that must follow, if the density of the population of New York City is allowed to increase at the present rate. If the medical profession only believes that the tubercle-bacilli *probably* bear a causal relation to tuberculosis, it still cannot afford to neglect measures that will destroy these germs, or prevent their dissemination. He therefore suggested (1) that each physician should lay down, for the management of individual cases, such rules as receive the sanction of those best informed on the subject; (2) that it should be the duty of every physician to report all cases of tuberculosis coming under his care to a central authority, which would then issue printed rules for the information of those attending these patients; and (3) that inspectors should be employed to inform and instruct the patients and their friends as to the manner in which the proposed measures were to be carried out. A combination of the first two indications was all that could be attempted at the present time. The rules referred to should call attention to the proper manner of disposing of the sputum and other discharges, the necessity of cleanliness of the mouth, and particularly in regard to the manner of expectorating, and the mode of protecting those parts of the bedding that are most likely to become soiled by the discharges. The rules should also point out the danger of healthy persons occupying the same room with the sick, the manner in which this room should be cared for when the patient is in the later stages of the disease, and how it should be purified after the patient has left it. Special attention should be directed to the manner of conducting health-resorts, so that healthy persons, and particularly persons convalescing from other diseases, should not be given rooms recently occupied by tuberculous patients. Proprietors of such resorts should be required to adopt adequate measures for disinfecting the rooms and the bedding, and to provide properly kept receptacles for the sputum.

In the absence of DR. JOHN S. BILLINGS, his paper on "The Prevalence of Consumption in the United States" was read by H. D. CHAPIN. By statistics it was shown that the annual death-rate from pulmonary tuberculosis for the census year ending June, 1890, was as follows in those States in which registration of deaths is the most complete: Connecticut, 2.34; District of Columbia, 3.59; Massachusetts, 2.67; New Jersey, 2.34; New York, 2.48; and Rhode Island, 2.66. From these figures it seems perfectly fair to assume that the number of deaths from pulmonary tuberculosis in the census year was over 125,000. For the six years ending May, 1890, the average annual death-rate from pulmonary tuberculosis was: In New York, 3.92; in Brooklyn, 2.98; in Boston, 3.86; and in Philadelphia 2.98; while in New York State, excluding New York City and Brooklyn, it was 1.81; and in Massachusetts, excluding Boston, it was 2.40. The influence of aggregation on the mortality from the disease is well marked. Estimating the average duration of pulmonary tuberculosis to be two years, he calculated that the number of cases of the disease actually existing at one time in New York City was 11,000; in Brooklyn, 4,000; and in the rest of the State, 13,000. Those localities that are especially frequented by the criminal and vicious classes are common centers of infection, and on this account the court-rooms are the most dangerous places, as they are crowded with this class of people, and the rooms are never effectually cleansed. Fortunately, however, these are just the places in which stringent prophylactic measures could be most authoritatively enforced. The medical profession should point out the necessity of providing in these places proper receptacles for sputum, and should direct that the rooms should not be swept while dry, but that the dirt should be gathered up with wet rags, and the floors cleansed with some disinfectant solution.

DR. ABRAHAM JACOBI said that as infants are usually infected with tuberculosis from external sources, it behooves the medical attendants to endeavor to secure a prompt cure of eczema, sore-throat, and catarrh, not only of the nasal passages and pharynx, but of the intestinal tract, and in this way minimize the chances of the tubercle-bacilli entering the system. Lesions of the bones, and particularly of the glands, should not be neglected, for a cervical adenitis is not infrequently the starting-point of a tuberculosis of the mediastinal glands. It should not be forgotten that one very likely source of infection in infants is the use of unboiled milk for their food.

DR. J. WEST ROOSEVELT thought the profession would accomplish much if it only succeeded in teaching the public the importance of simple cleanliness, and as an important step in this direction, the public should be instructed in the "art of spitting."

DR. A. H. SMITH thought that the public mind would best grasp the significance of the points brought out in this discussion, if it were made to understand that the two principal factors in the development of tuberculosis were the "seed" and the "soil;" and that although measures to limit the spread of the seed are important, they are no more important than efforts directed against the preparation of a favorable soil. The people should be made to understand that every habit of life that tends to depress the vitality is a factor in the formation of a suitable soil for the tubercle-bacilli. He had been impressed with the fact that in the rural districts where, at first glance, the surroundings seem most healthful, whole families would at times become victims of tuberculosis, and this susceptibility could only be explained by their conventional disregard of cleanliness and ventilation. Court-rooms may furnish a suitable place for the development of tuberculosis, but a still more fertile source is to be found in the post-offices in any large town. A post-office is one of the dirtiest places imaginable, and if, in addition to this, one or more of the large force of employés are victims of pulmonary tuberculosis, the mingling of their sputum with this dust exposes the other workmen to great danger of infection.

DR. C. G. CURRIER said that from a review of the literature of the past few years, he concluded that it is probable that heredity still plays a real and important part in the causation of pulmonary tuberculosis apart from predisposition. Although infants spend most of their time crawling about the floor, and are in this way especially exposed to inhalation of tuberculous dust, experience shows that tuberculous infection in infants most commonly starts in the glands, bones, or in the intestinal tract. Again, it is very rare for a husband to acquire the disease from a wife, or *vice versa*. Of 275 nurses that had been exposed to infection of tuberculosis, only two had acquired the disease in a period of twelve years.

DR. LAURENCE JOHNSON said that it had been proposed to put tuberculosis on the list of contagious diseases to be reported to the Board of Health. This would be unwise, for every physician knows what incalculable harm is likely to result to patients in the first stage of the disease from depriving them of that most important factor in therapeutics—hope. It has become firmly fixed in the minds of the masses, that pulmonary tuberculosis is a *hopeless* disease; while much has been done in recent years to shake this belief, but little effect has been produced except on the more intelligent classes.

DR. A. SEIBERT stated that he was much impressed by the case in which the infection had occurred from kissing, and expressed the hope that something would be done to break off this silly habit of kissing, which is so common among school-girls. It was perhaps significant that, in his experience, scarlet fever, diphtheria, and tuberculosis had developed much more frequently in girls than in boys.

THE PRESIDENT, in closing the discussion, said that it was the imperative duty of the Academy to instruct the public concerning the contagiousness of tuberculosis, and particularly in regard to the degree of contagiousness. Last summer a lady standing on the steps of Paul Smith's hotel was heard to say that she was glad she was so many miles away from the Adirondack Sanitarium, as she felt she was not so liable to develop tuberculosis. This remark shows that it is not enough to simply state the mere fact that the disease is contagious. Cleanliness is the keynote of the measures that had been advocated, and, in his opinion, it was the nasty American habit of expectoration that was largely responsible for the terrible ravages of the disease among us.

The Second International Congress of Dermatology will be held at Vienna from September 5 to 10, 1892, under the presidency of Kaposi.

CORRESPONDENCE.

CHICAGO.

The Illinois State Board of Health—Revocation of State Certificates—Railroad Transportation of the Dead—Typhoid Fever in Chicago, and its Relation to the World's Fair—Sanitary Work of the Police.

THE fifteenth annual meeting of the Illinois State Board of Health was held January 28th in the Capitol building at Springfield. Present: Dr. W. A. Haskell, of Alton, President; Dr. R. Ludlam, of Chicago; Dr. H. Williams, of Chicago; Dr. Griffith, of Springfield; Dr. W. F. Reilly, of Chicago, Secretary.

Among the matters of general interest upon which the Board took action was the revocation of State certificate No. 9490, issued January 30, 1890, to Dr. Samuel E. McCreary, then of Davenport, Iowa, subsequently of Peoria, Ill., and other places, and now advertising as having "permanently located" at Toledo. State certificate No. 8219, originally issued to Charles Rohning, M.D., of Brussels, Calhoun County, Ill., April 21, 1888, was also revoked on proof of Dr. Rohning's decease, and of the further fact that said certificate is in the fraudulent possession of Philip Simons, under indictment by the Grand Jury of Calhoun County for forgery and perjury, and who has been practising medicine under said State certificate.

The rules of the Board concerning transportation of the dead by railway or other public conveyance were revised so as to transfer corpses of those dead from diphtheria to the category of "absolutely forbidden." A number of cases where the transportation of diphtheria corpses had introduced the disease and caused fatal and widespread outbreaks, were reported by the Secretary as the cause for the act.

The following resolution by Dr. Haskell was unanimously adopted:

Resolved, That the position of special sanitary counsel to the Illinois State Board of Health be tendered to Dr. John H. Rauch, of Chicago, and that upon his acceptance of the position he be requested to make an investigation of the recent charge that Chicago is suffering from an epidemic of typhoid (enteric) fever due to a polluted water-supply; and, in view of the widespread publicity of said charges and their probably damaging influence upon the World's Columbian Exposition, the utmost expedition consistent with thorough investigation is urged.

The charge referred to in the above resolution was made by Professor William T. Sedgwick and Mr. Allen Hazen in a paper recently read before the Massachusetts Institute of Technology in Boston, from which we clip the following extracts:

"In the city of Chicago there has been for many years a large amount of typhoid fever. It was abundant, for example, in 1872, 1881, 1885, and in 1886. Between 1886 and 1890, however, it was less common; but in 1890 the death-rate from typhoid fever suddenly rose to a height almost exactly the same as that reached by Philadelphia in 1876, namely, 9.16 deaths per 10,000 of inhabitants and 4.16 per cent. of all deaths that occurred in that year. The actual number of deaths in Chicago in 1890 from typhoid fever was 1008. During the year just ended Chicago has reported 1977 deaths from typhoid fever, giving the prodigious death-rate for this disease of 16.64 per 10,000 of population and a percentage of all deaths of 7.19.

"In the month of May alone there were 408 deaths from typhoid fever. This number is more than one-fourth as great as the entire number of deaths from this disease the year before in the whole State of New York, containing 6,000,000 inhabitants. In the single month of May, 1891, there were more deaths from this disease in the city of Chicago than in the city of New York during the whole twelve months of 1888, 1889, 1890, or 1891. In 1891 there were 385 more deaths from typhoid fever in Chicago than in the previous year in the whole State of New York, with five times the population, and nearly 1400 more deaths than in London with three and one-half times the population of Chicago.

"The whole number of deaths from typhoid fever in Chicago in 1891 was 1997. Multiplying this number by ten, we have an approximate estimate of the whole number of persons affected by this disease. These extraordinary figures can scarcely be surpassed or even maintained in 1892 or 1893, but they must be a source of constant anxiety to the citizens, as they certainly are a menace to the sanitary success of the World's Fair.

"We copy from the official report of the Department of Health of the city of Chicago that typhoid fever was exceedingly prevalent in Chicago in 1872. We cannot agree with the author of the statement in the annual report of 1872 that, although the overcrowding and barrack-life incident to the months following the great fire in October, 1871, 'brought its legitimate result in an increased death-rate, yet during the year no epidemic existed.' The death-rate from this disease and its percentage of mortality to the total mortality were greater than have ever been since that time until the present epidemic had developed. After 1872 there was a marked improvement until 1879, when there was a slight increase, followed by a great increase in 1881. The fever subsided until 1885, when there was another marked increase, followed by a decrease in 1886, 1887, and 1888.

"In 1889 a rise began which attained the proportion of an epidemic in 1890, and reached the great height already referred to in 1891. It will be noticed that the epidemic in 1872 fell off very rapidly in 1873. That of 1881 declined much more slowly; that of 1885 more slowly still, so that unless some special effort is made to hasten the decline of the present epidemic, there is reason to fear that typhoid fever may continue to be very prevalent in Chicago in 1892–93.

"In the next place we may inquire whether, on the whole, typhoid fever has been increasing or decreasing in Chicago. An examination will show that for the eleven years, 1881–91, it has been much higher than for the preceding eleven years, and even omitting 1891, typhoid fever has, on the whole, gained ground in Chicago since 1880. This is true even if both 1890 and 1891 are omitted.

"The conclusion is inevitable that typhoid fever has, on the whole, materially increased in Chicago since 1880; while within the last two years it has risen to an extraordinary height. We may next inquire how Chicago

compares with other cities in respect to mortality from typhoid fever.

"The death-rate from typhoid fever of all the cities of Massachusetts, twenty-eight in number, for the twelve years 1878–89, was 4.62; that of Chicago during the same period was 5.85; that of Boston, 4.32; Worcester, Cambridge, and Lynn, 3.91. The averages for the whole State of New York, for the six years 1885–90, is 1.38. The average percentage for the city of Chicago during the same period was 3.27.

"From these facts it appears that typhoid fever has long been excessively prevalent in Chicago, and we have already shown that it is, on the whole, increasing, while within the last two years it has risen to extraordinary proportions.

"In a paper of this character we do not properly consider the causes of these facts. Nor would it be proper to attempt to analyze causes, but since it is now held by sanitary experts that the water-supply is the chief means of spreading typhoid fever, we may be permitted to look into the drainage and water-supply of Chicago. In the Board of Health reports of 1883–4, Commissioner of Health De Wolf, says: 'There can be no question but that the stream of filth coming through the city is a constant menace to the health of the citizens.'"

In view of all these facts the authors urge that active measures be taken to improve the sanitary condition of Chicago before the opening of the World's Fair.

At the afternoon session of the Board the following officers were elected for the ensuing year: Dr. W. A. Haskell, *President;* Dr. F. W. Reilly, *Secretary;* Dr. A. L. Clark, *Treasurer;* Drs. W. R. McKenzie and D. H. Williams, *Auditing Committee.*

Our City Health Commissioner, Dr. Ware, has publicly testified to the general worthlessness of the city's sanitary officers and incidentally commended the work of policemen as special sanitary officers.

Dr. Ware's testimony proves the importance of what the daily press has frequently urged, viz., that patrolmen on regular beats should be *ex-officio* sanitary officers. Especially in the residence districts should the police be charged with a general supervision of the thoroughness of cleaning alleys and streets. Such labor and the reporting of delinquents to headquarters would not be an irksome addition to a patrolman's duties and many would hail it as a relief from idleness.

A single policeman's badge of authority is often worth more than a dozen special "inspectors." The police force has habitually looked the other way, even in cases of flagrant violations of health ordinances, since public sanitation was intrusted to "inspectors."

It would be better to change the system entirely and give the police *carte-blanche* to enforce alley-cleaning regulations. The work would then be effectively done.

A FORM OF FELT JACKET.

To the Editor of THE MEDICAL NEWS,

SIR: The article in your issue of January 16, 1892, entitled, "Injury to the Spine: Invention and Application of a Paper Jacket," has prompted me to bring to your notice a form of jacket that I have been using for some time. In every instance I find it preferable to the plaster jacket, as it combines elasticity, firmness, and light weight.

I have had occasion to use plaster a great deal, and I believe that practice has enabled me to produce as light and rigid a jacket as it is possible to make, but I was led to search for something that was suitable alike to the infant and adult. This I found perfectly supplied in the adaptable porous felt, such as is ordinarily used for splints. The method of application is simple, and eminently satisfactory. An accurate mould of the body is taken by means of the plaster-of-Paris jacket, the patient being suspended. Before the plaster is entirely set, the cast is cut open in front. In this mould, a cast of the body is taken and allowed to harden. A piece of felt of suitable size is dipped in very hot water for a moment and quickly applied to the cast, and after having been gently beaten and pressed so as to conform to every line of the cast, is firmly held in place with muslin rollers and allowed to harden. This usually occurs within forty-eight hours. In this manner an exact mould is reproduced, showing every bony and muscular prominence. After trimming to fit, the spaces about the arms and hips being cut out, eyelets and laces are provided, and the jacket applied to the person during suspension.

The weight of the jacket is almost *nil.* It is firm and elastic. It is soft and porous, and fulfils every requirement of a spinal support.

To this cast may be added any form of apparatus that may be desired to give further spinal support or suspension. It may be readily reinforced by light steel strips, riveted to the sides. It may also be perforated, to give further lightness and ventilation.

While I do not claim any originality in introducing this form of jacket, I have not seen it used by anyone previous to the time that I first used it. Indeed, I have not seen this form of cast made use of by anyone, but was driven to search for something more suitable than plaster for infants and very young subjects who could not bear the weight of plaster, and in experimenting with various substances found this one to fulfil every requirement. As there is no special skill nor any particular tools required, the physician can at once see the advantages that this material possesses over any that is now in use.

I am confident that it is superior to any other material now in use, as it will stand any amount of rough usage; will not chip, break, or be bent out of shape.

The entire process is so simple, so readily performed, and gives such an inexpensive and satisfactory jacket, that I deem it worthy of your readers' attention.

CHARLES H. MERZ, M.D.

SANDUSKY, O., January 18, 1892.

NEWS ITEMS.

The Pan-American Medical Congress in the United States of Colombia.—Pursuant to nominations by Dr. Pedro M. Ibañez, of Bogota, member of the International Executive Committee for the United States of Colombia, the following organization of the Pan-American Medical Congress has been effected in that country: Vice-President, Dr. Pio Rengifo, New York. Secretaries of Sections—General Medicine, Dr. Ignacio Gutierrez Ponce,

Paris; General Surgery, Dr. Rafael Rocha Castilla, Bogota; Military Medicine and Surgery, Dr. Abraham Aparicio, Bogota; Obstetrics, Dr. Joaquin Maldonado, Bogota; Gynecology and Abdominal Surgery, Dr. Jose M. Buendia, Bogota; Therapeutics, Dr. Manuel Plata Azuero, Guaduas; Anatomy, Dr. Juan D. Herrara, Bogota; Physiology, Dr. Antonio Bargas Vega, Bogota; Pathology, Dr. Nicolas Osorio, Bogota; Diseases of Children, Dr. Antonio Gomez Calvo, Bogota; Ophthalmology, Dr. Proto Gomez, Bogota; Laryngology and Rhinology, Dr. Luis Fonnegra, Bogota; Otology, Dr. Carlos Esguerra, Bogota; Dermatology, Dr. Daniel E. Coronado, Bogota; Orthopedics, Dr. Juan E. Manrigue, Bogota; Naval Hygiene and Quarantine, Gabriel I. Castaneda, Bogota; General Hygiene and Demography, ———; Mental and Nervous Diseases, Dr. Pablo Garcia Medina, Bogota; Oral and Dental Surgery, Dr. Guillermo Vargas Paredes, Bogota; Medical Pedagogics, Dr. Jorge Vargas, Bogota; Medical Jurisprudence, Dr. Leoncio Barreta, Bogota; Auxiliary Committee (each member being the official representative of the Congress in his respective city), Dr. Nicolas Osorio, Dr. Andres Posada Arango, Dr. Jorge E. Delgado, Dr. Eugenio de la Hoz, Dr. Domingo Cagiao, Dr. Jose Manuel Rodrigues, Dr. Paulo Emilio Villar, Dr. Felix M. Hernandez, Dr. Rafael Calvo, Dr. N. Ribon, Dr. Nilceades Castro, Dr. Cayetano Lombana, Dr. Jose M. Martinez, Dr. Isaias Saavedra, Dr. Severo Forres, Dr. N. Villa, Dr. Evaristo Garcia, Dr. Miguel Caicedo, Dr. Emilio Villamizar.

The following medical societies have been elected as auxiliaries of the Congress, viz., Academia Nacional de Medicina, Academia de Medicina de Medellín, Sociedad de Medicina del Cauca.

The following medical journals have been designated as official organs of the Congress, viz., *Revista Médica*, Bogota; *Revista de Higiene*, Bogota; *El Agricutor*, Bogota; *Boletin de Medicina del Cauca*, Calá; *Anales de la Academia de Medicina de Medellín*, Medellín.

Medical Education in Turkey.—There are five medical schools in the Turkish Empire—one at Constantinople, one at Cairo, one at Aintab in Northern Syria, and two at Beyrout, one of the latter being Protestant and the other Roman Catholic. Only the Constantinople and Cairo institutions possess the right of granting licenses to practise; the other three, which are in the hands of missionaries, can only give certificates of study, candidates having to go to Constantinople to be examined. A diploma conferred by the Cairo school gives only the right to practise in Egypt; if a physician who has obtained a diploma at Cairo wishes to practise in other parts of the Turkish Empire, he must pass a further examination at Constantinople. The medical school of Constantinople was founded in 1883, and until now has educated some 1400 practitioners. The teaching staff comprises twenty professors, and the curriculum is of six years. The Protestant medical school of Beyrout has been in existence about twenty-two years, during which time it has educated 105 practitioners. There are six professors, and the length of the curriculum is four years. The other two schools are organized on a similar basis.

Professor A. Richet, a distinguished French surgeon, died recently in his seventy-sixth year.

Obituary.—Dr. Harmon W. Shove, of Woodbury, Conn., died of pneumonia, on January 23d, at the age of sixty-nine years. He was one of the most prominent practitioners in the section in which he lived. Dr. Shove was graduated from the Yale Medical College in 1853, and at once entered upon the practice of his profession at Woodbury. By his studious habits and almost unlimited capacity for work, he was, after nearly forty years of active service, still in the full and successful practice of his profession, which, by his unblemished life and dignity of character he helped to advance and elevate.

The Prevention of Adulteration in Russia.—A municipal institute for the analysis of food and drink has been opened at St. Petersburg. Rough qualitative analyses of milk, butter, bread, wine, beer, etc., will be made gratuitously for the public; but for more elaborate examinations of these substances, and of water, flesh suspected of trichinosis, preserved meats, etc., the payment of fees will be required.

The Correction of Prostitution.—An association has recently been founded at Budapest with the objects of combating the evils of prostitution, of redeeming its victims, and of establishing and maintaining a free dispensary for the treatment of poor patients suffering from venereal disease.

Matthew Berkeley-Hill, the distinguished English genito-urinary surgeon and syphilographer, died recently, in the fifty-eighth year of age. He was Hunterian Professor of Surgery and Pathology in University College and Dean of the Medical Faculty.

Ribbert, of Bonn, has accepted election to the chair of Pathological Anatomy in the University of Zurich, succeeding Klebs, who has resigned.

Albert James Bernays, lecturer on chemistry and toxicology at St. Thomas's Hospital, died recently, sixty-nine years old. The remains were cremated.

THE INFLUENCE OF HEREDITY IN THE PREVENTION OF DISEASE.

BY WOODS HUTCHINSON, M.D.,

PROFESSOR OF ANATOMY IN THE IOWA STATE UNIVERSITY, DES MOINES, IOWA

I HAVE ventured to call attention to this most important, but most difficult and indefinite subject, not with the hope of making any original additions to our knowledge of it, but simply to question how we are to interpret some of the facts already known and to provoke a general discussion of the subject in the light of wider and riper experience. We so often hear and read of the influence of heredity in the production and propagation of disease, and the subject in its concrete form is so frequently thrust upon us in our professional experience, that we are, I think, in no small danger of neglecting and almost forgetting the other and larger form of its action, and of regarding it as an almost malevolent rather than as a grandly beneficent influence. It is too often true, from the pathologist's as well as from the historian's point of view, that "the evil that men do lives after them, the good is oft interred with their bones." A few painful instances of inherited taint or predisposition are allowed to subtend a larger angle in our mind's eye than a silent host of cases of equally truly inherited immunity, or vigor that defies attack. Our most deeply rooted and fundamental characteristics have come down to us through a long, illustrious line of mammalian and pre-mammalian descent, by a rigorous selection and perpetuation of the useful and healthful results of heredity, and are not to be smothered or perverted by the upstart legacies of an odd generation or two of morbid action. The pedigree of the most aristocratic of diseases is but of mushroom length. The inheritance of abnormality of structure is rigidly self-limited, partly by the disadvantages at which it places its possessors and partly by the strong tendency of the system to revert to earlier and more vigorous and serviceable types. This tendency of our oldest ancestral traits to assert their supremacy we term the *vis medicatrix naturæ*—that sleeping lion to rouse which into action all our drugs and remedies are but as feeble stings and javelins. Heredity is not only vigorously limited in its influence for evil, but is the very basis of all remedial action. And, when we come to examine it closely, its evil influence is almost purely of a negative character—an absence of vigor, not the presence of a virus. Inherited deficiency suffers and cries out loudly for relief. Inherited vigor can take care of itself, and is silent with the great, calm silence of Nature. Are we not in danger of allowing our view of the question to be unconsciously influenced by this state of affairs even to the extent of regarding and speaking of disease as an independent entity with boundless powers of self-propagation and extension? We gloomily talk about disease being on the increase. We vehemently urge our legislators to prevent the marriage of consumptives, to restrain inebriates from propagating their kind, to forbid the bans of all whose pedigree shows the taint of insanity, as if the whole race were threatened with physical degeneracy, unless something be done to take the case out of the incompetent hands of Nature. We write of the consumptive, the neurasthenic, the epileptic, as a much-to-be-dreaded source of lasting danger to the community and to future generations, instead of as one whom Nature has branded with her verdict, "Weighed and found wanting" and marked for destruction. We seem almost to forget that even when the unfortunate sufferer escapes an immediate or directly fatal termination and succeeds in maintaining an existence for two-thirds or three-fourths of the natural term, of all his vital functions the reproductive suffers first and most severely, as is shown in the well-known infertility of wild animals in captivity, the suppression of menstruation in consumptive females, and the deadly abortifacient effect upon both sperm and germ of the syphilitic virus. When the vigor of the organism is sufficient to resist the tendency and to accomplish reproduction, a certain proportion of the offspring will revert to the healthier, sturdier type of their ancestors, while the major part of the remainder will be so handicapped by the lack of that vigor and resisting-power which their enfeebled progenitor could not impart to them, as either to perish during infancy or to break down under the strain of that grand rallying of all the vital forces for the act of procreation which marks the period of adolescence. Is not inherited syphilis, with its enormously increased mortality from the third month of fetal existence on, an example of the former method of elimination, and the tuberculous tendency, with its harvest-time just before or early in the reproductive

period, of the latter method? I think we are prone to underestimate the perfection of this check in the case of specific disease. The vast majority of ova impregnated during the period of active syphilization in either parent are destroyed before parturition, while of children produced, the few who, scarred and shattered, survive infancy seem every year to present a rapidly decreasing line toward extinction; in fact, in my own limited personal and hospital experience of some three hundred cases of hereditary syphilis, I do not believe that I have ever met with a case that had passed the age of thirty-five which presented the characteristic facial, ocular, and dental changes. Broadly speaking, all disease is self-limited, either in the individual or in the family.

In order to arrive at some practical estimate of the actual connection between heredity and disease as we find it already existing, I have endeavored to collect some statistics bearing upon the history in respect of the three great maladies to which the term "hereditary" is generally though somewhat loosely applied, and by which the welfare of posterity is supposed to be most seriously threatened, viz., insanity, tuberculosis, and carcinoma.

In regard to the first of these, it need hardly be said that it is an open question if we have any right or reason for regarding it as a disease or distinct pathologic entity in any strict sense of the term, any more than lameness, blindness, or general debility; yet as it is generally most vehemently denounced as such and declared to be the one dark shadow on the future of our civilization, I shall make no further apology for so treating it. Through the kindness of my friend, Dr. G. W. Hill, of the State Asylum at Independence, I have succeeded in obtaining reports of some fifty public institutions for the care of the insane in all parts of the United States, with an aggregate of over 54,000 inmates. Of this number, 5093 cases, or barely 9.4 per cent., are recorded as "hereditary," or in other words as having had one or more insane relations. Of course, this figure can only be taken as a very rough estimate of the condition of affairs, on account of the difficulty of obtaining accurate or reliable histories of the cases previously to their entering the asylum; indeed, some superintendents refuse to classify their cases according to cause, while a few even omit heredity entirely from their list of causes. Although in some cases, for instance, in comparatively recent immigrants, almost no family history can be elicited, while in others the patient's relations will from family pride even endeavor to conceal the existence of other "skeletons in the cupboard" among their mutual kindred, yet in many instances no such motive exists, the family being ready to tell all that they know and even more for the sake of getting someone to take charge of the unruly sufferer. On the other hand, the existence of a lunatic or "queer body" in any family is a decidedly macroscopic symptom to the eye of the dullest observer. Like murder, insanity "will out;" and when we consider that many of these cases have been duly and elaborately examined and passed upon by a public commissision that could call as many witnesses as it might desire, I think we may fairly claim that this record represents at least the major proportion of all cases in which such a coincidence existed. Even supposing that mental unsoundness in the family was discovered in only half the cases in which it actually existed, we should still be distinctly below the 22.6 per cent. which represents the proportion of cases in which heredity is recorded as a factor in the total aggregate of the English and Welsh asylums. This fact, together with the strikingly excessive proportion of patients of foreign birth in our institutions, would seem to me to go far to prove that the much-lamented increase of insanity in this age and country is in no sense attributable either to heredity or to the cumulative effect of civilization upon successive generations, but is principally due simply to the sudden and excessive changes of physical, social, and political environment to which our immigrant, and to a lesser degree our native, population has been subjected. Statistics upon this subject are scarce and difficult to obtain, and what few I have been able to collect seem rather to shake one's confidence in the popular belief that "figures won't lie" than to give any reliable and consistent information, the reports before mentioned varying from as low as 0.6 per cent. to 35 per cent. of hereditary influence. Maudsley found hereditary predisposition in 16 of 50 cases; Trelat in 43 of 73; a report to the French government in 1861 gives 530 of 2000 cases; Jacobi reports 24 of 220; Hagen discovered "direct hereditary predisposition" in 26 of 187 cases, and Mitchell in 20 of 64—a total of 659 in 2594, or a trifle over 25 per cent., apparently attributable to hereditary influence. Estimates are somewhat more numerous, but vary almost as widely: Burrows regards hereditary predisposition as the cause of six-sevenths of all cases; Moreau, of Tours, of nine-tenths; Martini of nearly one-third; Esquirol of one-fourth in the poor, of three-fifths in the rich; Bergmann of one-third; Emmert of 75 per cent.; Maudsley of "more than a fourth but less than a half;" Marcé of nine-tenths; Leidesdorf of 25 per cent.; Hill of one-fourth—making an average estimate of 52 per cent. of hereditary influence.

With all due respect to the authorities quoted, I am afraid one can hardly help being struck with the fact that the majority of the "estimates" begin almost where the "figures" leave off, and continue

onward and upward to perilously near the pinnacle of 100 per cent., and that data showing 25 per cent. are hardly a sufficiently solid basis for computations reaching over 50 per cent., even though quoted as such. Would it not seem highly probable, upon even this meager showing, that our generally accepted conception of the mischievous influence of heredity in this important field is in need of serious revision? The wider the range of investigation is made and the more completely local or personal sources of error are eliminated, the smaller becomes the apparent importance of heredity as a factor, while the common estimate of over 50 per cent. of malevolent influence seems to be supported by data to the extent of barely 10 per cent.

Of course, it goes without saying that these figures by no means represent the total number of cases in which suspicious or morbid family history existed, for there must have been many others in which, from various causes, it was impossible to elicit it; but, on the other hand, it must be remembered that the terms "hereditary predisposition" and "family influence" are very loosely used and in many cases really mean nothing more than that one or more of the patient's numerous relatives or ancestors has been insane, or even epileptic or inebriate, a fact which may have no connection whatever with the case in question, excepting an historic one. If every family in which a case of mental aberration can be ferreted out is to be regarded as predisposed, how many of us will escape suspicion? The mere fact that one of the patient's relations or even ancestors has been insane is no more necessarily the cause of his insanity than would the fact of his grandfather having been lost at sea be the cause of his meeting death by drowning. *Post hoc* is by no means always *propter hoc*, although I think that we are often apt to regard it so in hereditary pathology.

When we come to consider carcinoma, the second great morbid process in which heredity is declared to be a factor, its apparent influence shrinks to still narrower limits. Hardly any two estimates agree, not even those given at different times by the same authority, but their range of variation is much less striking than in the case of insanity. Definite data of any kind seem even scarcer and more difficult of discovery, a tolerably extensive review of the literature of the subject in the Library of the Surgeon-General resulting only in the mere handful which I have to present. S. W. Gross finds hereditary influence in 10.3 per cent. of his cases; Lebert traces it in 10 of 102; Paget traced the disease to other members of the family in 78 of 322 cases, and in another series of 160 cases found hereditary tendency in 26; Sibley finds 34 instances of heredity in a collection of 305; West, 8 of 49 cases of uterine carcinoma, and Von Winiwarter 5.8 per cent. in his list of cases of mammary carcinoma; Velpeau finds an inherited predisposition in one-third of his cases, while Parker found such family history in only 56 of 397 cases. I have succeeded in getting a report of only one of the hospitals devoted specially to the treatment of this disease, the Brompton Cancer Hospital of London, which gives the proportion of cases having relations who are affected with carcinoma as 10.3 per cent. in their grand total of 28,638 patients in thirty-seven years.

A highly suggestive bit of collateral evidence in the same direction is the fact given by Brannan in his most interesting analysis of 2000 consecutive deaths in the experience of the Washington Life Insurance Company, that of the 56 cases having carcinoma in their family history (41 of whom had lost a parent by this disease), only one, or 1.79 per cent., died of carcinoma, while of the remaining 1944 having no such history, 67, or 3.45 per cent., fell victims to it. This unexpected preponderance of mortality, of course, is probably accidental and due to the small number of predisposed cases; but it certainly would not have been thus were heredity a really appreciable and active factor in the disease.

The evidence is scanty, but tolerably harmonious so far as it goes, and I think it would be safe to say that the tendency of the best thought of modern authorities on this subject is decidedly in the direction of seriously doubting whether heredity plays any appreciable part as a factor in the production of carcinoma. Indeed, one can hardly help wondering how such a widespread belief in the importance of hereditary influence in carcinoma came to be built up on such an apparently slender basis, especially when we remember that the figures given probably represent nearly the full proportion of cases in which a suspicious history actually existed. Here there is comparatively little tendency to concealment or falsification, on the part either of the patient or of her relatives; on the contrary, we will be told at the outset of our inquiries, with what seems almost like a morbid pride, that "there is cancer in the family." Indeed, I am half inclined to believe that we have unconsciously imbibed the major part of our belief on this subject from the laity. Merely upon *à priori* grounds one would hardly expect the organism or any part of it to be born old, and yet senility of tissue from extinction of function would seem unquestionably by far the most potent, if not the only proved predisposing cause of the carcinomatous process. The uterus undergoing involution, the atrophying mamma, the puckered lip wrinkling over the toothless gum, have all either temporarily or permanently outlived their usefulness, become supernumeraries,

pensioners on the body at large, and these are the breeding-grounds of 70 per cent. of all cases of carcinoma.

When we attempt to approach the "white plague of the North" from this standpoint, the problem becomes a well-nigh hopelessly speculative one, on account of the vastness of the field and the utter inadequacy of definite information obtainable. Estimates are legion, but figures are few, and so nearly equally distributed, from 10 per cent. to 70 per cent. in single series, as to fail to inspire much confidence in their reliability. I have written to the medical directors of some four or five of our leading life insurance companies, asking for references to data bearing upon the question. Their replies have been most prompt and courteous, but all practically to the same effect: collections of cases are so few and on so microscopic a scale that, as one of them frankly says, "We have almost ceased to regard statistics as of practical value in the selection of life risks." Text-books and monographs on pulmonary tuberculosis usually carefully avoid statistical statements, and when the rule is relaxed it is principally to ring the changes on the fossil figures of Louis, Lebert, Barthez, *et al.* My researches have been far from exhaustive, but the results have been most disproportionately and distressingly meager. And yet, so far as they go, and biased as many of them evidently are, they fall far short of supporting the commonly accepted view of the question. There is probably no disease that both the profession and the laity are more confidently and unanimously agreed in ascribing largely to hereditary influence than "consumption." Our poor starveling, flat-chested patient assures us that she knows there can't be anything "wrong with her lungs," because "there is no consumption in the family." Of six intelligent and experienced practitioners, taken at random, approached on this subject, four gave it as their opinion that from 70 per cent. to 90 per cent. of all of their cases were traceable chiefly to heredity, while the other two placed the proportion at 40 per cent. But before giving the actual figures obtained, it may perhaps be as well to briefly consider their probable value on general principles. In the first place, they are likely to be fairly exhaustive and complete as far as they go. The patients are usually under observation for considerable periods of time; are not only not in any way incapacitated by their condition for either remembering or relating the facts of their history, but are above the average in intelligence and conscientiousness. "The good die young," usually of pulmonary tuberculosis, and it is almost a question whether we are not entitled to regard conscientiousness as one of the leading morbid symptoms, so well-nigh invariably is it found in conjunction with pulmonary tuberculosis. There is but little motive for concealment, so that the percentages probably represent almost the total of those having such flaws in their family history in each group investigated. On the other hand, in no group of morbid histories is it more imperative ever to keep in mind that *post hoc* is by no manner of means *propter hoc*. A very brief mathematical statement of the case will illustrate this at once. According to our mortality-rates one-seventh of our population ultimately dies of pulmonary tuberculosis, *ergo* any individual who could recall the histories of seven deceased ancestors or relatives would have the right, if we may use the expression, by the law of averages, to one ancestor dead of pulmonary tuberculosis, without being under any peculiar suspicion of "consumptive taint." The smallest possible family group must consist of six members, two parents and four grandparents, but when the investigation is extended, as it frequently is, to brothers and sisters, uncles and aunts, it may include from ten to thirty members, among whom it would be strange if one or more had not fallen victims to this commonest cause of death. What wonder, then, if the enthusiast upon heredity—and most of those who prepare tables are enthusiasts—is able by perfectly legitimate means to make a most imposing display of facts that apparently support his theories to the letter. But what most seriously impairs the scientific value of these tables is the fact that in a considerable minority, if not in a majority of them, the fundamental term itself denotes not merely a morbid process, but the degree of that process—in other words, that "consumption" means not merely "tuberculous degeneration," but tuberculous degeneration sufficiently extensive to seriously threaten life, or even in the usage of some authorities "tuberculous degeneration ending in death." It is by no means uncommon to hear or read such expressions as: "Mr. A. was threatened with consumption in his early days," or "Mr. B. had all the symptoms of phthisis at one time," "*but he recovered.*" I think we are inclined to markedly underestimate the prevalence, and if I might use the expression, the naturalness of this simple reversion to the ameboid state on the part of certain of our tissue-cells. Now that Von Ruck, Trudeau, and other modern therapeutists, are assuring us that from 60 per cent. to 80 per cent. of cases of pulmonary tuberculosis in the earlier stages are curable, and that pathologists are informing us that over 30 per cent. of bodies dead of diseases other than tuberculosis have fibrous or calcareous deposits, evidently of tuberculous origin, in the lungs, the prevalence of even that aggravated stage of the process which is termed consumption would appear to be much greater than is usually believed. A mortality of 40 per cent.—a maximum one—would give it a morbidity of nearly 35 per cent.—indeed some authorities

claim 50 per cent. of the race as suffering from it at some time in their lives. When the process appears where we might expect it—in those areas in which cell-proliferation is most active and the tissues most nearly in their embryonic or ancestral condition, the corpuscle-breeding areas of the lymphatic glands—we dub it "struma," and place it in a separate column; when it originates in the next most active cell producing areas—the great serous membranes—we call it meningitis, peritonitis, or pleurisy, as the case may be; in the cells of the bone-marrow "osteitis," but taking all these altogether as mere modifications of the same process, it really seems that it would be well-nigh as logical to speak of "hereditary" gastritis, eczema, or coryza, as of hereditary tuberculosis. So enormous is the extent of its prevalence that it seems almost entitled to rank as one of the primary fundamental reactions of living tissue—the starvation reflex.

Of the data attainable, the oldest are those of Louis, Gialussi, Rilliet, Barthez, and Lebert, who report respectively 11 per cent., 10 per cent., 14 per cent., and 16 per cent. of all their cases (actual number not given) as presenting this factor. Piorny, Ancell, Pidoux, and Walshe go a little higher, and find heredity present in 25 per cent. of all their cases. The average keeps rising. Hérard and Cornil give 38 per cent., Briquet 40 per cent., Miller, Cotton, and Bodendahler 50 per cent., Homan 70 per cent., Portal 75 per cent., while Rufz caps the climax with 83 per cent.

The tables in which the actual numbers are given do not vary over quite so wide a range, but there is still plenty of the "spice of life" in them. Koranyi, in 900 cases, finds heredity in 20 per cent.; Leudet, in 500 cases, in 50 per cent.; Carl von Ruck, 35.4 per cent. in 301 cases; Herman Brehmer 36 per cent. in 13,000 cases (Görbersdorf Institute); Detweiler, of Falkenstein, 35 per cent. in over 6000 cases; Brannan, 23 per cent. in 350 cases; Smith, 70 per cent. in 1000 cases. In round numbers this makes a total of 22,000 cases, with an average percentage of 37 per cent. This is a very considerable proportion, yet when we contrast it with the result arrived at by Brannan—that, of 2000 risks accepted by the Washington Life Insurance Company, at an average age of thirty-five years, 22.4 per cent. had hereditary tendency to consumption (a percentage which would certainly be greatly increased if the rejected risks, earlier ages, and both sexes were included), it seems to me far from conclusive, and certainly fails to support the usually accepted views on the question. There is, of course, no doubt that the existence of a severe or fatal degree of tuberculosis in a parent distinctly increases the probability of such a process appearing in the offspring. In Brannan's table, 27 per cent. of those showing "hereditary tendency" died of tuberculosis, as against 16 per cent. of those showing no such tendency. But it would seem more probable that what the offspring inherit is merely the lowered vitality of which tuberculosis is a symptom, rather than any specific tendency to this special form of degeneration. The "consumptive" is physiologically below par, from his undersized heart and dilated stomach to his clubbed finger-tips.

Defective nutrition is a more powerful factor than heredity, as shown by Brannan's tables, for, of the 690 cases, with no hereditary tendency whatever, that were below the standard weight, 30.7 per cent. died of tuberculosis, as against 27 per cent. of 252 cases of all weights having such hereditary tendency; while, more significant still, of those having such tendency who were above the standard weight, only 6 per cent. died of tuberculosis, as against no less than 48 per cent. of those of this group who were below standard weight. In other words, a mere increase of fifteen pounds in weight seems capable of annulling the strongest hereditary tendency, for the 6 per cent. mortality of the heavy-weights among the predisposed is within a fraction of the percentage in the same class of the non-predisposed.

To sum up roughly, we find a tainted pedigree—

Among 57,000 cases of	insanity,	in 10.1	per cent.
" 30,000 "	carcinoma,	" 10.5	"
" 22,000 "	tuberculosis,	" 37.3	"

These estimates are, of course, made on far too narrow a basis to be regarded as in any way conclusive, and their reliability for positive purposes is open to serious question in many particulars, but I think they at least justify us in demanding, in answer to the charge that heredity is, in any sense, a prominent or active factor in the production of disease, the Scotch verdict of "Not proven."

On the other hand, all the remedial power of Nature, individual and racial, all the vigor that defies attack, all the priceless immunity from disease, all the exquisite harmony with environment that surrounds us on every hand, are the direct results and illustrations of the law of heredity. Its beneficent effects are innumerable and unquestionable; its injurious effects few and doubtful.

Rheumatoid Arthritis. — BLAKE (*Provincial Medical Journal*, 1892, xi, 121, p. 11) expresses the view that a proportion of cases of rheumatoid arthritis are dependent upon some form of intoxication, in consequence of which the nervous system suffers secondarily. He therefore recommends that in a given case a careful search should be made for a source of poisoning from within or without. This found and removed, the circulation is to be supported, mental strain relieved, and nutrition maintained. Passive motion and massage, conjoined with electricity, should be energetically employed.

A CASE OF BILATERAL EMBOLISM OF THE MIDDLE CEREBRAL ARTERY.[1]

BY D. N. EISENDRATH, A.B., M.D.,
RESIDENT PHYSICIAN, COOK COUNTY HOSPITAL, CHICAGO.

THE patient is S. M., an Englishman, thirty-six years of age. There is no history of any cardiac trouble, rheumatism, or syphilis in himself or his family. He smokes to excess, drinks but little, and is by occupation a peddler, and obliged to be out in inclement weather.

For the past two years he has at intervals had quite severe pain of a dull, aching character in his ankles, unaccompanied by any swelling and also by any pain in other joints. During the past six months he has had almost constant headache, referred to vertex, and has noticed marked dyspnea and rapid action of the heart upon the slightest exertion, so that he was unable to peddle. For the relief of these symptoms he came to the hospital.

The patient, upon admission, was well-nourished, but pale. There was marked visible pulsation of the carotids and temporals, which were tortuous to their very termination. The radial pulse was full and bounding, rate 110—a typical Corrigan or water-hammer pulse.

A loud murmur was heard over the carotids and femorals, and in the latter an almost complete double murmur. A few moist râles could be detected over the larger bronchi. There was marked diffuse pulsation of the entire precordial region at each systole. The apex-beat was visible in the sixth left interspace—one inch to the left of the left mammary line. It was strong and heaving. The area of dulness was increased in all directions. Auscultation revealed at the apex a musical see-saw murmur, both systolic and diastolic sounds being replaced—the diastolic murmur being louder and more blowing in character, the systolic murmur being transmitted to the left. Over the pulmonary area the second sound was accentuated. Over the aortic area, a long, loud musical diastolic murmur was heard, that, being followed to the apex, gradually decreased in intensity so that the second murmur heard at the apex was the transmitted aortic murmur. There was a trace of albumin, and a few pale hyaline casts in the urine.

During the time that the patient was under obsertion he frequently complained of severe vertical headache and of attacks of vertigo, which were relieved by nitro-glycerin, gr. $\frac{1}{100}$, and caffeine citrate, gr. v, every four hours. No digitalis was given at any time, the hypertrophy of the left ventricle being sufficient to compensate for the valvular trouble. About four days before the patient's death, it was observed that the respiration was of a stertorous character; the patient could not be aroused, and coma developed. The pupils were equal, somewhat contracted, and feebly responsive to light. Supra-orbital pressure caused a contraction of the muscles of the left side of face, arm, and leg. The right naso-labial fold was obliterated, the right arm and leg fell perfectly lifeless, when released after being raised; there was apparently complete paralysis of the voluntary muscles of the right side of the face, of the right arm and leg. The respiration was irregular, almost Cheyne-Stokes in character, and stertorous. On account of the accompanying heart-disease, and the probability that a vegetation or calcareous mass had been detached, a diagnosis of embolism of the left middle cerebral artery was made. When the patient was examined twenty-four hours afterward, there was no response to supra-orbital pressure; both arms and legs, when raised and released, fell lifeless, as if paralyzed; there was now complete bilateral hemiplegia.

Ophthalmoscopic and electric examinations were unfortunately not made. The patient remained in this condition of deep coma, with irregular Cheyne-Stokes respiration for forty-eight hours longer, the character of the radial and temporal pulses and of the intra-cardiac sounds remaining unchanged. Death occurred very suddenly, the pulse, a few moments before, having been 120, full and bounding.

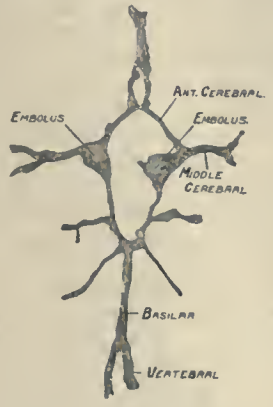
The post-mortem examination, thirty-six hours after death, showed evidences of hypostatic congestion in the posterior portions of both lungs. The pericardial cavity contained ℥viii of clear yellowish fluid. There were a few "soldier spots" upon the visceral pericardium. The coronary vessels were markedly tortuous, but pervious. The veins were congested, both on the anterior and posterior surfaces of the heart.

The aortic valves were incompetent to the water test. The valves were irregular in outline, and when approximated left a considerable interval between their free edges. They were covered with freely detachable calcareous vegetations, so that each valve was a mass of cauliflower excrescences; some of the latter were softer, more like masses of ordinary fibrin, and had not undergone calcareous change. The aortic orifice was narrowed. The mitral valve was so incompetent as to admit four finger-tips; the free edges were smooth; there was an elevation in the middle of the anterior cusp, the convexity of which was directed toward the left auricle; it was somewhat conical in shape, with an opening on the ventricular surface of the valve leading into a cavity, showing this to be an aneurism of the mitral valve. The cavity of the left ventricle measured 11 cm., its wall 20 mm.; there was thus marked excentric hypertrophy. The right ventricle was also hypertrophied.

The *membranes* of the brain were markedly congested, but not adherent or thickened. Upon dissecting out and opening the vessels of the circle of Willis, a calcareous embolus was found, as shown in the annexed illustration, at the intra-cranial termination of each internal carotid artery, situated at the point of origin of the middle cerebral arteries in such a manner as to completely occlude the lumen of both these vessels. The distal portion of each was empty and the vessel-walls were very anemic. The emboli were also so situated as to completely prevent the entrance of blood into the anterior cerebral arteries at their origin from the internal carotids.

[1] Read at the meeting of the Cook County Hospital Clinical Society of Chicago, November 5, 1891.

There were extensive areas of softening in the interior of the brain, bilateral and symmetrical, involving the corpus striatum and optic thalamus, and in the brain-substance surrounding the lateral ventricles on all sides, viz., the frontal, upper part of the temporal, the ascending parietal and the frontal convolutions.



The blood-supply of the brain is derived from the vertebral and carotid arteries; and the mode of origin of the left carotid explains why embolism should be more frequent on the left side. In the case reported the first embolus was undoubtedly that on the left side, causing right hemiplegia. The left carotid arises directly from the highest part of the arch of the aorta, and its course is almost a direct continuation of the direction of the current of blood in the aorta, whereas the right carotid comes from the innominate, which arises from the aorta at an angle with the course of the aortic blood-current. Hence clots washed from the cardiac valves pass more readily into the left carotid than into the right. The consecutive embolism first of the left and then of the right is easily explained, and yet is extremely interesting. The circle of Willis, it will be remembered, is formed by the two posterior communicating arteries, which pass one on each side from the internal carotids to the posterior cerebrals, into which the basilar divides, and by the anterior communicating artery, between the two anterior cerebrals of the internal carotid. The latter divides on each side into the anterior and middle cerebral, and from these and the posterior cerebral the blood-supply of each hemisphere is derived.

From the circle of Willis and the commencement of the three cerebral arteries, small branches arise that supply the central ganglia of the hemisphere and the adjacent white substance, while the three arteries themselves ramify over the surface of the brain and supply the gray cortex and the greater part of the white matter of the hemisphere. Between these central and cortical systems there are no anastomoses, nor do the central branches communicate with each other, so that embolism of a main vessel, like the middle cerebral, would lead to extensive anemic necrosis or softening.

The central arteries consist of two medial and four lateral groups, two on each side; the latter supply the chief part of the central ganglia, and the anterior lateral arise at the beginning of the middle cerebral arteries and supply the internal capsule, lenticular and caudate nuclei, and optic thalamus.

Of the supply to the cortex, that of the middle cerebral is the most extensive. This vessel divides opposite the island of Reil into four branches, which have the following distribution:

I. Third or inferior frontal convolution.

II. Lower two-thirds of ascending frontal and root of middle frontal.

III. Whole of ascending parietal, and superior parietal lobes, and part of inferior parietal lobe.

IV. Remainder of inferior parietal and posterior part of first two temporal convolutions.

From this last branch, near its origin, one or two large branches arise, which supply the greater part of the first and second temporal convolutions. The anterior cerebral supplies the remainder of the frontal lobe, the quadrate or lobus precuneus, gyrus fornicatus, and marginal convolutions of the mesial aspect. So that the extensive bilateral softening found post-mortem was in perfect accord with the experimentally determined area of distribution of the anterior and middle cerebral arteries.

In most cases of cerebral embolism the plug comes from the heart, and its source is either diseased valves, or vegetations that have been detached and carried along with the blood-current. The embolus may come from either the mitral or aortic valve, more frequently from the former, and especially when there is mitral stenosis. Embolism is most frequent between later childhood and middle life. There has usually been some antecedent cause for the endocarditis, *e.g.*, rheumatism, chorea, or scarlet fever. As in the case reported, the signs of organic heart disease are almost always to be recognized previously to or at the time of embolism.

An immediate exciting cause is rarely to be traced. In the case reported the patient had passed a comparatively quiet night in bed, and was found comatose, without any prodromal symptoms except an increase of headache. The plug in a case of embolism may consist of fibrin (usually decolorized), of vegetation, soft or firm, from a cardiac valve; sometimes of a calcareous mass from a valve of the heart.

The embolus is usually arrested where the artery is narrowed by giving off a large branch, very often at a bifurcation, as shown in the specimen. The middle cerebral arteries and their branches are the most frequent seat of embolism, because they are the direct continuation of the carotids.

In the case in question the emboli, which were calcareous vegetations, are lodged at the very termination of the internal carotids, so as to occlude both the anterior and middle cerebral arteries.

In rare instances only—one case being reported by Carrington[1]—have both middle cerebrals been obstructed. The effect of this almost simultaneous blocking was to cause an extensive area of anemic necrosis or softening, which pathologically represents broken-down nerve-elements separated by an effusion of serum.

The focal symptoms in the case were quite characteristic of a plugging of the middle cerebrals, viz., first, right hemiplegia, indicating embolism of the left side; then, twenty-four hours after, left hemiplegia, showing an obstruction on the right side. Whether aphasia was present or not it was impossible to determine. Bilateral obstruction is rarely simultaneous, but sometimes occurs in quick succession, as in the case reported. The differential diagnosis is especially to be made from cerebral hemorrhage and thrombosis. The prognosis in such a case as this is necessarily grave. Treatment is not likely to be of much avail.

CEREBRAL THROMBOSIS, WITH REPORT OF TWO CASES.[2]

BY G. W. McCASKEY, M.D.,
PROFESSOR OF THEORY AND PRACTICE OF MEDICINE AND CLINICAL DISEASES OF CHEST AND NERVOUS SYSTEM, PORT WAYNE COLLEGE OF MEDICINE (MEDICAL DEPARTMENT TAYLOR UNIVERSITY) PORT WAYNE, INDIANA.

CHARCOT has with much truth said that he that is master of the circulation of the brain, is likewise master of cerebral pathology. This, of course, is not because of any lack of importance on the part of the structures through which the vessels pass, but because, in the first place, a thorough and accurate knowledge of the intra-cranial vascular system of necessity implies familiarity with the different vascular areas supplied or drained by any particular blood-channel; and in the second place, because lesions of the vessels constitute the pathologic basis in the large majority of all cases of cerebral diseases.

I have been frequently impressed with the belief that too little attention has heretofore been given to the venous as compared with that given the arterial circulation of the brain. Arterial lesions are, of course, more frequent than venous; but thrombosis and phlebitis of the cerebral venous channels, which usually go hand in hand, even if of less importance than the arterial, are still of sufficient moment to often compromise the life of a patient.

Two cases that have recently fallen under my observation have especially excited my interest in this subject, and I will first present a brief record of them.

CASE I (not seen during life).—Mr. S. D. M., aged forty-five years, an insurance agent; a heavy-set, active business man; had never suffered from any serious illness. On November 28, 1890, while standing at the head of the stairs at his residence, he slipped and fell, feet forward, striking his head on the steps as he went down. When he got up he appeared very much dazed, and said: "Let me get out doors." He returned in a short time, feeling very faint. Immediately afterward, and for about ten days succeeding the accident, he complained of pain in his head and back and frequent nausea, and he often vomited. During these ten days, he was in bed the greater part of the time. He often complained of a peculiar pain in his head, as though something was moving around in it, without designating just where. There were, unfortunately, no data showing his condition as to fever, circulation, etc., during that time. Subsequently, he went to his office and attended to his business, making frequent complaints, such as he had made while in bed at home. The nausea and vomiting persisted.

On the morning of December 17th, when about to set out for his office, he remarked that he was feeling badly, and that they need not be surprised if he should come home before evening.

On the 18th, he did not go to his office at all, but, as before, complained of nausea, pain in the head and in the back.

About half-past one on the morning of the 19th of December, his wife left the room to attend to a sick child. He expressed his disinclination to have her leave, because he was himself feeling badly, but said perhaps she had better go. She returned quietly to his room at three o'clock, when he was breathing regularly. She again returned at five o'clock and found him unconscious, with stertorous breathing.

A physician was summoned shortly after the discovery of his unconsciousness; the pupils were not markedly contracted, but the breathing was somewhat slow. No other information was obtained, the coma being then very deep and terminating in death at noon, December 19th.

On the morning of December 20th, at nine o'clock, the family requested Dr. Howard McCullough and myself to examine the skull and brain in order to ascertain whether there was any gross lesion of traumatic origin that would account for the death. We found the body well nourished; rigor mortis well marked; no external evidence of injury. Upon reflecting the scalp we found, almost in the center of the vertex, an ecchymotic spot about the size of a silver quarter, just beneath and involving the periosteum. Upon removing the brain we found marked adhesion of the dura mater of the convexities along the margins of the longitudinal fissures. The sinuses of the dura mater were obviously diseased. The lining membrane of the superior longitudinal and left lateral sinuses especially were roughened and covered with strongly adherent and

[1] Path. Soc. Trans., vol. xxxv, 1884, p. 108.
[2] Read before the Michigan Southern Medical Society.

coagulated blood. In the left lateral sinus an ante-mortem clot, firmly organized and about one-fourth of an inch long, completely blocked the sinus and terminated at the extremity in soft, dark blood of post-mortem deposition. The pia mater was intensely congested. The dependent portions of the ventricular cavity contained a considerable quantity of bloody serum—enough to very nearly fill the horns. Nothing further of an abnormal character was discovered upon coarse dissection of the brain. No microscopic examination was made, because of the sudden illness of myself before the brain had been placed in a preserving fluid.

CASE II.—On June 14, 1891, I was called in consultation with Dr. H. D. Wood, of Angola, to see Miss B. O., aged twenty-four years, and obtained the following history: The patient's health had always been good, except that from childhood she had been subject to sick headache. When a child she also had a discharge from the ear. Recovery from this was complete, and was never followed by any recurrence. About four months ago she had what was thought to be the grippe, though she did not go to bed or call a physician. Her symptoms were severe headache and general aching, lasting a few days. From this she made a fair recovery, but it was evidently not complete, for she remained weak and her family think there was progressive loss of flesh. About the first of May, 1891, Dr. Wood was called, and found her with a temperature of 101° and a pulse-rate ranging from 70 to 100. Since that time she has not been free from fever of about the same intensity. About the first of June (two weeks before I was called in consultation) she was seized with violent headache that persisted up to the time of my visit. There had been some nausea and a little vomiting. There were no obvious disturbances of motility, sensation, vision, or hearing, although no careful tests were made.

On June 13th, she grew apathetic, and gradually passed into a state of coma from which she could not be aroused.

At the time of my examination, she made no response to loud calls close to her ear. The conjunctival reflex was almost entirely abolished, and the pupils were moderately but evenly contracted and entirely irresponsive to light. There was no strabismus or nystagmus. There was marked edema of both eyelids, with moderate but still very perceptible exophthalmos. There was also considerable distention of the veins of the forehead; the left external jugular vein was very prominent. There was but slight response to a pin-prick on the feet, and the plantar reflex was abolished. I did not see the patient again, but she was very carefully watched by Dr. Wood, who reports that there were no new symptoms manifested, but an intensification of all the symptoms mentioned. The coma became deeper, the edema of the eyelids greater, the exophthalmos more marked, the distention of the veins of the forehead more prominent. Death occurred four days after my visit.

I made a diagnosis of cerebral thrombosis, probably of the marantic type, and gave an absolutely unfavorable prognosis, in which Dr. Wood fully concurred. I was especially anxious to be able to test the diagnosis by the findings of a post-mortem examination, but, though Dr. Wood made every effort to secure one, he was unable to do so.

In these two cases, in one of which the diagnosis was made during life, with no opportunity to verify it after death, and in the other discovered only upon post-mortem examination, we have illustrations of what I am inclined to think would be found much more frequently than is supposed, if the symptomatology were more fully understood, and the disease therefore more easily recognized. In running through the literature of this subject as contained in the standard text-books of the times, we are met with extremely vague and unsatisfactory clinical pictures to serve as the bases of diagnosis. By some authors the subject is treated as only of pathologic interest, and the consideration of the symptoms, because of their vagueness, is dismissed in a few words. The time has come when this position is not fully, if at all, justfied. There are certainly many cases of cerebral thrombosis in which the diagnosis can be made with as strong a degree of probability as obtains in many another well-recognized disease. In the attempt to study these symptoms upon an anatomic and physiologic basis, we must bear in mind that the venous channels known as sinuses of the dura mater are extremely complicated and quite extensive in their anatomic relations, and most diverse in regard to the importance of the structures with which they are severally in relation. The effects, therefore, of occlusion of one of these channels at any particular point would depend upon the anatomic and functional importance of the structures the venous blood of which travels toward the heart through this particular channel, and also upon the facilities for carrying the current through collateral avenues. When the superior longitudinal sinus is involved, headache is usually a prominent symptom, owing doubtless to the retardation of the blood-current from certain parts of the intra-cranial structures. In addition to this we have distention of the veins of the mucous lining of the nose, and epistaxis, therefore, becomes of frequent occurrence. The close relation of the petrosal sinuses to the mechanism of the ear points to their involvement when brain-symptoms follow certain forms of ear-disease. The blocking of the lateral sinuses would cause more or less complete obstruction of the current through the superior longitudinal sinuses. Turning now to the basis of the brain, we find wonderful provisions made for carrying on the circulation if one channel becomes obstructed. The sinuses upon opposite sides of the median line are united by transverse channels of large size, and in addition the anterior extremity of the system terminates in a large and important vein known as the ophthalmic,

which, passing through the orbit, is placed in direct communication with the external jugular through the facial vein.

The anatomic relations are thus extremely fortunate, from a diagnostic standpoint. For instance, the obstruction that prevents the blood from passing out of the ophthalmic vein, in a backward direction, gives rise to very definite and characteristic symptoms. Among others, there are distention of the frontal veins, edema of the eyelids, and exophthalmos. There are, of course, at the same time functional disturbances of the retina, ranging from slight amblyopia to complete amaurosis, with abolition of the light-reflex. Another circumstance that occasionally enables us to recognize occlusion is the very curious anatomic arrangement by which several very important nerves, namely, the third, fourth, and sixth, actually penetrate the wall of the cavernous sinus and pass through it on their way to the muscles that they supply, separated from the venous blood within the sinus by its lining membrane alone. It at once becomes very obvious that occlusion of the blood-current in the cavernous sinus, with the attendant outward pressure that must necessarily follow, by reason of the pressure exerted by the forces of the circulation through the capillaries, might very easily compromise the function of any or all of these nerves. In this way ophthalmoplegia, ptosis, or strabismus may become strongly corroborative symptoms in establishing the diagnosis. It is not my intention to review this extensive field in detail, but rather to point out a few of the more important and better established facts upon which we may fall back in establishing a diagnosis of cerebral thrombosis.

In the first of the foregoing cases, the question of diagnosis is, of course, not involved, and we may turn at once to the unfortunately imperfect clinical picture that we are able to obtain. Briefly, then, we may assume that occlusion of the left lateral sinus and plastic inflammation of the lining membrane of the superior longitudinal sinus gave rise to a train of symptoms of a fairly well defined character. The absence of a careful scientific study before death can, of course, be only vainly regretted. We know, however, that there had been persistent headache, with nausea and general malaise. Of the circulation and temperature, until within a brief time prior to death, we know nothing. Anatomically we find the pia mater, which normally pours its venous blood into these venous channels that had been obstructed, intensely congested, and we find further evidence of interference with the circulation by the bloody effusion, with which the ventricles were well distended, in symptoms and phenomena of circulatory obstruction.

In the second case, the diagnosis of thrombosis of the basal system rests mainly on six symptoms, namely: distention of the frontal veins, edema of the eyelids, exophthalmos, great distention of the left external jugular vein, abolition of the light-reflex, while unconsciousness, with slight fever, was, of course, corroborative of the existence of inflammatory action undoubtedly involving the lining membrane of the sinuses. I hold that in this case the diagnosis is positive, and taken in connection with the first case and the cases that have been reported, principally in Russia and Germany, will, I trust, assist in forming a rational foundation for the diagnosis of this not very rare, but rarely recognized affection.

Since writing the foregoing, I have seen another case that I think belongs in the same category.

On November 21, 1891, I visited Mr. L. T., in consultation with Dr. J. W. Cartwright, of Payne, Ohio, of whom I obtained the following history: About ten days previously the patient had been seized with a severe attack of facial erysipelas. This had run its usual course, and had yielded to the ordinary treatment. At the time of my visit there was practically nothing left of the dermatitis but the customary residual hyperemia and coarse desquamation.

Alarming brain-symptoms had developed in the last twenty-four hours, and I found the following conditions present: There was external squint, incomplete ptosis, nystagmus, comparative dilatation of the right pupil, and intense injection of both conjunctivæ. There was also partial coma, and hyperpyrexia, the temperature at the time of my visit being $106\frac{8}{5}°$. The patient died two hours later.

In this case the specific process had travelled along the radicles of the facial vein, and through their relation with the ophthalmic, along this to the cavernous sinuses. A similar connection has been reported in several published cases, in which a specific dermatitis had produced a phlebitis of the sinus by extension through the channels referred to. A very interesting case of cerebral thrombosis involving the left cavernous sinuses has recently been reported by Destot (*La Province Méd.*, Lyons, 1891, No. 24). In this case the specific process originated in an acniform pustule of the nose that was apparently benign. Like the last of my cases reported, it emphasizes one of the dangers of specific inflammation of the parts contiguous to the brain.

Tracheotomy in an Infant Four Days Old.—CLEGG (*British Medical Journal*, No. 1619, p. 68) has reported the case of an almost moribund infant, *four days old*, in which he performed tracheotomy on account of the presence of a large nevoid mass beneath the tongue, rendering respiration almost impossible. The child lived for thirty-six hours, but finally died.

SYSTEMATIC USE OF THE EYE IN TEACHING ANATOMY.[1]

BY W. P. CARR, M.D.,
OF WASHINGTON, D. C.

IN this iconoclastic age, a sentiment seems to be growing among medical men that lectures are of little use for didactic purposes. I wish to enter my protest against this idea, and to point out what I consider an important method of enhancing their value. The aim of the lecturer, I take it, is not so much to teach anatomic details that are much better learned from books and dissections, as to teach the student, first, how to study, how to understand, how to fix in mind the broad outlines and principles of the laws of morphology, the meaning of structures; and, secondly, to teach him those methods of observation that will enable him to add the necessary details for himself. In doing this we all recognize the importance of engaging the eye as well as the ear of the student. I have become more and more convinced of the importance of a systematic appeal to the student's eye and ear at the same time, and more and more convinced that word-pictures alone, no matter how forcible and true, make but comparatively dim and transient impressions upon the brain. Most anatomic facts are remembered by means of mental pictures—mental photographs upon the brain. Suppose you wish to remember the shape of some object. You call up a mental picture of it that you have, at some former time, stored away in your brain. Not only so, most of these mental photographs are composite photographs, made by numerous impressions, placed one over the other. Especially is this the case when the object to be remembered is a familiar one; and frequently, blended in the general outlines of the picture, and yet distinct, you may recognize some individual object of the class you wish to recall. Let me mention the great trochanter of the femur. Immediately there rises before your mind's eye a representation of the upper end of that bone. You see the trochanter, its position, shape, and relations; and most likely you recognize in the composite the outlines of some particular femur that you have handled oftenest, or, that diagram in your Anatomy that so frequently meets your eye. These facts show, I think, that it is by means of composite mental photographs that we retain the memory of form, memory of relation, and memory of position. The important question is how best to produce and fix these images.

Naturally, different persons possess in very different degrees this power of mental photography, as is evidenced by the ease with which some recall the features of absent friends, and the utter lack of such ability in others. But I am sure the faculty can be cultivated and brought to a satisfactory degree of efficiency in all, or nearly all persons. To do this we must begin with simple figures, and gradually add details. Everyone can remember such simple figures as the cross, square, circle, etc., but few can carry in mind a complicated arabesque. I think the older anatomists had some such idea in mind when they tried to find in the bones fanciful resemblances to familiar objects. They were trying, perhaps unconsciously, to use some simple image already formed upon the brain, as a durable basis upon which to build a more elaborate composite. But the idea may to great advantage be carried much further. I shall never forget how, when beginning the study of anatomy, I was helped in fixing the human ethmoid by a few chalk-marks placed upon the board by my professor, Dr. Elliott Canes. Simply a cross, to represent a front view of the vertical plate and christa galli, and the horizontal plate, and an oblong mass of white suspended from the arm of each cross, to represent the lateral masses. By comparing this image with the bone itself, a mental photograph was formed too simple ever to be forgotten. Having formed, in this way, a simple, durable image, it becomes an easy matter to modify it in detail. We may add the turbinal processes, the ossa plana, show their relation to the orbits and the frontal bone, and having gone as far as convenient with the chalk, refer to more elaborate diagrams for details, and finally let the student finish by studying the bone itself. And how much more intelligently he can do it, after we have prepared him in this way by giving him a simple, durable, but plastic image as a basis, and by explaining to him the morphologic significance of the bone, as well as other interesting and practical facts relating to it. All the other bones may be treated in the same manner. The superior maxilla, for instance, may be built up on a triangular pyramid; the scapula upon a triangular prism, corresponding exactly to the triangular rod of cartilage from which it is developed, and even a bone of as variable form as a vertebra may be illustrated in such manner that a composite mental photograph of it is formed in which all of its variations are recognized, from the stunted tip of the coccyx to the typical dorsal vertebra, or the occipital bone, and even the other vertebral segments of the skull.

The ruder the drawing the better, for we do not now wish to impress the shape of the component parts, but the shape of the bone as a whole, and the relative position of its parts simply represented by masses of black and white.

There are, however, some things that cannot be illustrated by even the most carefully prepared flat

[1] Original abstract of a paper read before the Association of American Anatomists in Washington, September 23, 1891.

picture. Such things as the facial nerve in the aqueduct of Fallopius, the ventricles of the brain, the fissure of Sylvius, cannot be drawn satisfactorily upon a plane surface. It is impossible to show the thing itself to a large class of students, on account of its small size. In such cases we must resort to models large enough to be seen from all parts of the room. It will not answer to have a small model in the hands of each student, unless, with a pointer, we have a demonstrator stand over each student as the lecture proceeds. For teaching purposes I have a large, rough model of the left side of the brain, made of papier-maché, five feet long, and yet light and easily handled. It is rough and apparently simple-looking, and yet I can show upon it the relative position and general shape of nearly every important part of the brain, both internal and external. I conceived the idea of making it, mainly to show what I cannot show in diagrams, the lateral ventricle, particularly its descending horn, the manner in which the pia mater enters to form the choroid plexuses, the velum interpositum, etc., and the fact that the five vesicles of the fetal brain remain distinct in the adult.

My conclusions are:

1. That we remember form, position, and relations by means of mental photographs.

2. That these are composite photographs.

3. That they may be easily modified from time to time, but cannot be easily effaced or radically altered.

4. That these images are formed by the eye, and understood through the ear.

5. That the power of mental photography varies in different persons, but may be cultivated in all, or nearly all, to a satisfactory point.

6. That the way to do this is to produce, first, a very simple impression, which, consequently, will be durable, and then more and more complicated images, that will not only coincide with and strengthen the first, but will, at the same time, add the necessary details.

7. That in doing this the primitive designs are best drawn upon the blackboard before the student's eyes; and that, afterward, a series of large diagrams should be used, or models in case diagrams are not satisfactory.

8. That the student is by these means taught how to appreciate and study Nature for himself in a calm, scientific, and observing manner.

The Prophylaxis of Scarlatinal Nephritis.—In more than a hundred cases of scarlatina seen in the course of six years, in which the patients were for three weeks kept upon a milk diet, ZIEGLER has not once encountered nephritis as a complication.—*La Semaine Méd.*, No. 4, 1892.

ORIGINAL LECTURE.

ELEPHANTIASIS ARABUM OF THE LEG; LIGATION OF THE FEMORAL ARTERY; RECOVERY: SUBSEQUENT PHLEBITIS AND THROMBOSIS; SEPTICEMIA; DEATH.

A Clinical Lecture
delivered at the Buffalo General Hospital, Surgical Clinic, November 21, 1891.

BY PROF. ROSWELL PARK, M.D.

ALBERT J., thirty-six years of age, came to the Buffalo General Hospital in October, 1890, giving the following brief history: Fourteen years ago he fell from a trapeze, and injured the right hip and iliac region. He suffered pain and soreness in the part for a number of weeks, after which time he resumed his work as wood-carver. Not until six months later did the present swelling commence, and the enlargement of the limb since then has been gradual but constant. It has finally attained such proportions as to force the man to give up his occupation. He has never suffered from any constitutional disease. The family history is excellent. He has never had upon the leg any ulcer or fissure of the skin from which fluid has escaped.

This brief history is all that is attainable, but it is, perhaps, sufficient for present purposes. I expose the lower part of the body and show you the tremendous difference between the right and left lower extremities. In order to have measurements for subsequent comparison, I will use the tape-line and give you the circumference at the following points:

		Right.	Left.
Ankle	(inches)	13½	9
Knee	"	22½	15
Middle of thigh	"	28½	20½

You will observe no ulceration anywhere about the skin, although around the middle of the leg there is great thickening and roughening of the epidermis, which presents quite a corneous appearance. There is nothing else for which this condition can be mistaken. We have here to deal with a case of elephantiasis Arabum, or the common form of elephantiasis known by the name pachyderma, and, also, from its frequency in the West Indies, as Barbadoes leg. The condition, virtually, is a hypertrophic affection of the dermal and subdermal tissues, with enormous thickening of the skin and more or less edema. Such a condition as is here presented is quite rare in this region, although very frequent in the tropics; in fact, the disease in any such form as this is well-nigh unknown in Buffalo. I have seen a similar affection confined to one hand and forearm in a young man, at the time an inmate of the penitentiary, and I am familar with a case in an adjoining town of a decrepit elderly woman, whose feet and legs, up to the knees, are involved in a similar condition. These three cases comprise my entire experience in eight years in western New York.

Pathologically, the disease, when of the acquired form, begins as an inflammatory affection of the bloodvessels, which sometimes is so acute as to cause a violent cellulitis resembling erysipelas, at other times so chronic as to

be accompanied by virtually no inflammatory phenomena. The cases in which the lower limbs are involved nearly always begin with acute manifestations. This is not quite true of elephantiasis of the genitals, of the upper part of the body, or of the face. The lower extremities and the external genitalia are by far the most commonly affected regions. In various treatises you will see pictorial representations of extreme cases of this condition; for instance, where one or both legs are so enormously enlarged as practically to confine the patient to the recumbent posture; also cases in which the scrotum is so involved as almost to touch the floor, hanging like an immense bag between the limbs, and where the penis is entirely lost in the thickened integument, only a minute opening and an excoriated groove marking the site where the urine escapes. In females the labia and the clitoris are similarly affected. But such instances as these are rarely seen outside of hot countries, and they have most frequently been reported from India. In such cases as this before you, the disease usually begins as a cellulitis with excessive edema, and with lymphangitis and perilymphangitis, often even with phlebitis and periphlebitis. Above the limit of swelling, purplish-red lines will often be seen extending toward the trunk, showing the implication of the lymphatic vessels. It is common in such instances to get a history of recurring inflammatory attacks, by each of which the preëxisting condition is made worse. As these cases progress, the epidermis becomes very much thickened in spots, and papillomatous outgrowths of large size, such as you see upon this man's limb, appear. As the surface becomes thus hardened and corneous, fissures or cracks are formed, which extend, to become excoriations and even foul ulcers, from the former of which a thin serous fluid dribbles or oozes, this fluid being pure or nearly pure lymph; while from the ulcers there comes a discharge of thin sanious pus. In ill-nourished patients, and in those careless in the matter of personal cleanliness, this condition may become offensive and disgusting. There is little pain, patients complaining for the most part merely of the augmented size and weight of the part involved, suffering but little, unless a fissure extends down to a point where a nerve is exposed, in which case we have to deal with an acutely irritable fissure or ulcer.

So far as the causes of elephantiasis are concerned, we may divide them into two categories and state that elephantiasis may be of congenital or of acquired form. Both of these forms are practically connected with the lymphatic system. Whenever you have the opportunity, I advise you to consult a somewhat rare little book by Dr. Busey, of Washington, upon *Congenital and Acquired Malformations of the Lymphatic System*, which is a perfect mine of curiosities and clinical facts relating to the subject of this lecture. As you well know, varicosities of the lymphatic vessels may occur congenitally, just as they do in the venous system, while at other times the lymphatics are congenitally deficient or some anomalous condition exists by which their proper channels of communication with the central lymph-stream are cut off or obstructed. It is possible that from some such cause as this an infant may be born with the beginnings of this malady implanted within it, but it is not so much of the congenital as of the acquired form of which I wish to speak to you. Of this form we may say that it is always inseparably connected with some impediment to the return of the lymph-stream, whether this be in the lymph-vessels, in the bloodvessels, or in the surrounding tissues. In this particular case, I imagine that, as the result of the injury which this man sustained many years ago, there was either a rupture of the principal lymph-trunk of this extremity, or some intra-pelvic inflammatory or thrombotic condition, by which the return of lymph from this leg was gradually impeded, as the result of which obstruction the present condition has been slowly engendered. I can find no other explanation for it in his case. It may happen to you to find in some other case, which will remind you of this, a history of some such trouble as phlegmasia alba dolens or of long-standing varicosities, with subsequent phlebitis and thrombosis, resulting in venous and subsequent lymphatic obliteration, or of some more or less extensive ulcer that has become inflamed and has set up a train of disastrous sequelæ, or of some injury such as fracture, penetrating wound, violent contusion, or something of that kind. Whenever this disease is mentioned there comes naturally into one's mind that affection which, before all others, is its most frequent cause in tropical climates. I allude to the presence in the system of a parasite known as the filaria sanguinis hominis, which is a very minute, thread-like worm, upon which the researches of Manson have thrown a flood of light and the life-history of which he has revealed. It appears from his studies that the microscopic embryos of this worm abound in drinking-water in regions where the disease is best known. This water is taken into the system; the embryos fail to be killed by the digestive juices, but pierce the intestinal wall and are taken up with the products of digestion by the absorbents. Once having gained an entrance in this way, they select the lymphatic vessels as their habitat, and here they manifest a peculiarity that has no analogue that I recall in the study of disease in man. Within the innermost recesses of the lymph-nodes and lymph-vascular organs they hide, as it were, during the active working and waking hours, but at about sunset they emerge from their hiding-places and are then found in the lymph and especially in the blood, where they sport and play until about the hour of sunrise, when they retire for the day, again to go through this diurnal or rather nocturnal program. There is nothing chimeric or fanciful about this account. Filaria disease has been carefully studied both in England and in India, and hundreds of observations attest the truth of these statements. The disease has even been experimented with in this way: By making those subject to it sleep during the daytime and work or keep awake at night, the program given has been exactly reversed; in other words, the filariæ disport themselves in the blood during the hours of rest and sleep, and retire completely from observation during the hours of activity. These statements do not constitute a digression from the subject of this lecture, but serve to explain the most common etiologic factor in the production of this disease the world over. It is by the presence of these minute organisms within the lymphatic vessels that there is set up a condition of chronic inflammation, of dilatation, and of obstruction of the natural lymph-channels that slowly brings about this enormous distention and hypertrophy of the

soft parts. In the case in hand, however, inasmuch as this man has never been in tropical climates and presents the disease in one limb only, there is no reason to suspect that we have here to do with the results of filaria disease.

So far as diagnosis is concerned, there is virtually nothing else for which such a condition as this can be mistaken. One has to decide really only between the congenital and the acquired form, a matter that the history of the case at once settles.

So far as life is concerned the prognosis is usually not bad; the question in such cases is mainly as to how long the patient can tolerate or survive the anatomic condition with which he is handicapped; but so far as recovery is concerned, the prognosis is bad, there being but little, if any, possibility of any such happy termination. On the contrary, there is rather danger of a continuance of growth, together with the disastrous results of greater and greater separation from the source of nutritive supply and of the occurrence of sequelæ, such as ulceration, including the various phenomena of septic phlebitis and of sepsis in other of its various manifestations. With great care and attention to cleanliness, with rest of the part, and perhaps with such applications as shall keep the epidermal surface anointed and prevent the formation of fissures and excoriations, patients may be made reasonably comfortable, although the real progress of the disease be not stayed.

So far as radical treatment or cure is concerned, it can only be applied in one of two ways—either by complete ablation of the part, or by cutting off the principal channel of nutrition and, as it were, starving the limb. In 1851, the late Dr. Carnochan, of New York, first suggested in such cases as this the ligation of the principal artery of the lower extremity. He carried this out with some measure of success, and his practice has found imitators in all parts of the globe. The principle upon which this surgical treatment is based is good; we run the risk, however, of overdoing that for which we are striving, and there is always danger of sloughing or even of gangrene from the operation.

In the present case, this man has worn bandages and elastic stockings of various design and manufacture, and he thinks that by the continuous pressure that they have exerted the rate of growth of the leg has been somewhat checked; but he has now reached a point where it is no longer possible for him to pursue his trade, and he desires to have done whatever offers any prospect of restoring his usefulness or else of terminating his career; and he has accepted very gladly the proposition made to him to have the femoral artery tied, although I have not failed to set forth to him the unpleasant possible results of such an operation. Accordingly, he presents himself before you to-day for this purpose. The operation has nothing about it peculiar, save that in such a case as this, in which the pachydermatous condition extends so high in the groin, the operation will be mechanically more difficult, although, I apprehend, no more dangerous.

The operation was performed October 25, 1890, under ether. The prediction with regard to the mechanical difficulty of the ligation of the femoral artery below Poupart's ligament was justified by the fact that it lay at such great depth. The necessary incision had to be made much longer than usual, and only after penetrating to a depth of three inches was the artery reached. In other words, the artery had to be tied at a depth corresponding to the length of the index finger. Otherwise the operation passed off without incident. It was made after the usual aseptic manner and the wound was covered with aseptic dressing. The limb was wrapped in cotton-wool and placed on a single inclined plane. The patient recovered from the procedure without accident or particular delay.

One month after the operation that was performed in your presence, I show you the patient with elephantiasis, in order that you may judge for yourselves of the result. I recall to your minds the measurements taken upon a previous occasion, and repeating them, I enable you to see that there has been a decrease in the circumference of the knee and thigh of very nearly five inches. The circumference at the ankle has decreased only an inch and a half, or perhaps two inches. You may judge of the man's general condition for yourselves, and you hear his statement to the effect that he moves the leg with much less sense of effort. He expects now to leave the hospital within a couple of weeks, and he has promised to return after a while and submit himself once more to your inspection.

January 20, 1891. The promise that this patient made to you upon the occasion when you last saw him has been fulfilled, but in quite an unexpected way, for this time he is brought into the clinic-room upon a stretcher and in almost an unconscious condition. He left the hospital as he intended; he went back to work; but from some cause, concerning which his present condition prevents us from learning, he was brought in by the ambulance yesterday in a semi-delirious and irrational state of mind, with high fever and with the appearance of the limb that I shall show you. You see that it is now once more enormously swollen, and it presents every local appearance of inflammation, especially along the course of the superficial veins; you will note that the skin is red and very edematous, and that he can scarcely move the limb at all. I am thus unable to tell you how this has occurred, but I show the case to you now as one of intense phlebitis, with every evidence of thrombosis and of septic infection, and I may say now that his condition is one that justifies a most unfavorable prognosis. Were it not that he can be moved without visible suffering, I should hardly have ventured to bring him before you. I imagine that with his present condition he cannot live forty-eight hours. To just what extent this accident depends upon the result of the operation I am quite unable to say. Certainly, as you know, he was temporarily benefited by the operation, and was perfectly satisfied with its immediate results. There was no phlebitis at that time, and I imagine that he has either been intemperate or careless about exposure, or both, in order to bring about the state of affairs that you see here.

The patient died about thirty-six hours after he was exhibited to the class. An autopsy revealed a condition of septic phlebitis with general septicemia. There were no metastatic abscesses. The right lower extremity was enormously enlarged; the integument and subcutaneous tissues were thickened, hanging in folds. The arch of the diaphragm, on the right side, reached to the fourth inter-

costal space; on the left side to the sixth rib. The pleuræ were free and normal, save for a few slight bands at the right apex.

The pericardium was normal. The heart weighed thirteen ounces; the aorta and pulmonary valves were competent. Behind the tricuspid valve was a well-organized clot. The endocardium and myocardium of the right side were normal. The left endocardium was deeply injected (not post-mortem staining), otherwise normal. There was slight atheroma. The aorta, the aortic valves, and the mitral leaflets were slightly injected. The left lung weighed nineteen ounces. It was emphysematous and edematous, and presented minute petechiæ beneath the pleural surfaces.

The bronchial mucosa was injected. There were patches of atheroma in the bronchial vessels (pulmonary); minute infarctions in the right lung; general emphysema, and edema of the lower portions.

The left kidney weighed nine ounces; the capsule was adherent, the cortex diminished, and markedly injected. The right kidney was like the left.

The spleen weighed thirteen ounces; it was soft, enlarged. The liver was fatty. The skin of the right lower extremity was much thickened, and with the subcutaneous tissues hung in folds from the leg. There was an increase in the fibrous septa of the subcutaneous tissue. The femoral (right) artery was excised at the point of a former ligation (two months previously), showing a well-organized clot. The collateral circulation was carried on by the profunda.

A cause of the elephantiasis was not found.

Examinations of skin, under the microscope, showed that the epidermis was enormously thickened, with a marked increase of connective tissue in the cutis vera, this last having widely dilated lymph-spaces; there were several areas of small round-cell collections in the connective tissue of the true skin. About the vessels of the lungs there was a marked increase of connective tissue, similar to that of the skin; this was also edematous.

CLINICAL MEMORANDA.

A CASE OF PARALYSIS FOLLOWING MEASLES.

BY JAMES STRATTON CARPENTER, A.M., M.D.,
OF POTTSVILLE, PA.

THE rarity of occurrence of paralysis as a sequel to morbilli has been fully shown by Dr. H. B. Allyn, in a recent number of THE MEDICAL NEWS, wherein the author was able to collate only forty-one cases of this disorder after a most extended research. In a practice of ten years I have seen but a single case, which, until I met with Dr. Allyn's article, had been well-nigh forgotten. I desire to place this on record, as adding one more to the number of cases thus far observed.

Gertrude E., a child of three years of age, was treated by me for a mild attack of measles, two other children in the house being sick with the disease at the same time, and in an equally mild form. Three weeks prior to the outbreak of measles, I had treated them for a mild scarlatinal trouble, which had been fully recovered from before the measles had appeared. On the third day of the child's illness the mother noticed that she was breathing heavily, and found it impossible to arouse her from the stupor in which she lay. Being sent for hurriedly, I found the little patient in high fever, with stertorous breathing, and apparently unconscious, but she was able to answer my questions, although she immediately relapsed into stupor. I had her placed in a lukewarm bran bath, and prescribed appropriate remedies. Within thirty-six hours I had the satisfaction of obtaining a renewal of the favorable conditions that had preceded the attack, and in a few days more the girl was convalescent. The first attempt to walk, however, revealed an inability to lift the right foot, which was dragged after its fellow in efforts at progression; the same motor disturbance was discovered to have affected the right arm, after I had been summoned; this had hitherto escaped attention because of the child having always been left-handed. The loss of co-ordination was shown in the child's attempts to pick up small articles from the floor, the hand not only being unable to grasp the object, but being projected forward with some violence, or to either side of its destination; and, finally, when anchored safely at the objective point, after successive trials, the sound member was called to the aid of its palsied fellow to secure the desired article in full possession.

The cause of this palsy was not at all easy for me to ascertain at that time, nor was the solution of the problem decided upon at all satisfactory to myself. That paralysis could follow measles pure and simple I had never been taught to expect, nor had my reading ever furnished me with any example of this sequel of morbilli. I had been unable to discover the slightest trace of diphtheritic trouble in the entire progress of the case, and when informed that the child had had a spasm prior to my reaching the house, at the time of the occurrence of the unfavorable symptoms noted, I was particularly careful to reëxamine the throat, fearing lest some implantation of a diphtheritic character had occurred. I discovered nothing more than the usual congested condition of the fauces that is always found in this disease. But paralysis after measles *without diphtheria* as a causal factor seemed hardly admissible, and my conclusion, therefore, was that a *concealed* post-nasal diphtheria was responsible for the disturbance, and I so stated to the family.

That there was ample excuse for not having a too familiar acquaintance with this sequel of measles is readily shown if we consult the pages of Pepper's *System* in reference to the "complications" and "sequelæ" of morbilli, which, according to the writer of the article in question, "it is a difficult matter to dissociate." Under "complications" he says: "Among the more common disturbances of the nervous system convulsions play an important *rôle*. The epileptoid seizures of the prodromal stage generally terminate favorably, but in some cases of a malignant character the onset of the disease may be ushered in with fatal convulsions. Convulsions *in the later stages are apt to have a lethal termination* (italics mine), as they usually occur in connection with some grave complication, *particularly of the thoracic organs.*" And under the head of "sequelæ" we find this most important subject dismissed in a single phrase: "and, lastly, various derangements of the nervous system." That the writer, in the preparation of the article, had access to a wide range of authorities is shown in a foot-

note to the title of his essay, yet surely, if clinical evidence is to be regarded, "convulsions in the later stages" are by no means significant of "a lethal termination," unless, as Dr. Allyn says in his article, they should be "repeated," and even under these circumstances they but "increase the gravity of the prognosis, both as regards life and as regards the recovery of power in the palsied members." "Convulsions in the later stages" of measles, then, should never fail to attract attention to the possible occurrence of this rare form of cerebral palsy. In my own case it was not discovered until the child renewed its attempts at walking, *after* convalescence had apparently been established, the coincidence of the child's left-handedness, in this instance, with a right-sided palsy, preventing an earlier discovery of the lesion.

The treatment pursued was the administration of strychnine in ascending doses, beginning with gr. $\frac{1}{60}$ and reaching to as large a dose as gr. $\frac{1}{16}$, three times daily, before recovery was effected, which was complete. There was no aphasia present in this case.

A CASE OF NON-TRAUMATIC HEMORRHAGE INTO THE SPINAL CORD.

BY J. JOSEPH KINDRED, M.D.,
FIRST ASSISTANT PHYSICIAN AT THE PENNA. STATE LUNATIC HOSPITAL, HARRISBURG, PA.

EXCEPT in respect to its very rapid termination, the following case in its clinical course and history presents a rather typical instance of non-traumatic spinal hemorrhage.

The patient, J. G., an intellectual married man, fifty-nine years of age, had been in good health up to the date of the present trouble, excepting for occasional severe attacks of intercostal neuralgia.

He was well-built, rather muscular, always temperate and active in his habits. There was positively no history of syphilis or of any long illness. A few hours previously to the first symptoms of the spinal hemorrhage, he had attended to business with his usual enthusiasm, and expressed himself as feeling unusually well. At the moment of the appearance of the sudden pain and other symptoms he was making some mental effort, not amounting, however, to any unusual strain. Without any prodromal sign he fell forward on the floor, at first seeming very slightly stunned as if from shock, but not losing consciousness, even momentarily. Placing his right hand to the cardiac region he complained of having there excruciating pain, which from his description resembled that of angina pectoris. There were also pain in the dorsal region, spinal tenderness, and the "cincture feeling" over the chest and abdomen. After walking with assistance into an adjoining room, a feeling of beginning numbness in the lower extremities was complained of. Thorough examination showed much anesthesia below the fifth dorsal vertebra, with beginning paralysis of the muscles connected with the segment of the cord to which the pain had been referred. The reflex excitability was diminished. Three hours after the initial symptom, respiration was much disturbed; the pain, almost agonizing at first, had greatly subsided, while the power of motion in both legs was completely lost. The implication of the spinal centers controlling the bladder and bowels was indicated by the patient's inability to expel either urine or feces. That the hemorrhage had occurred high up in the dorsal region was suggested by persistent priapism and by intestinal flatus, showing paralysis of the splanchnics. The temperature was normal; the pulse 98. The abdominal and other muscles concerned in respiration rapidly became paralyzed; the respiration grew more and more labored until death ensued—six and one-half hours from the beginning of the attack. The usual course of treatment had been pursued. One point of special interest was the very rapid termination of the case. In his work on *Nervous Diseases*, Dr. Allan McLane Hamilton states that he has never seen a fatal termination in such cases within several days, and doubts if such could be the case, unless the hemorrhage should occur at a very high point, involving a number of the intercostal nerve-roots; he further says that even this is improbable. Dr. Hammond, however, takes the opposite position, and this case, as the autopsy shows, certainly seems to sustain the latter view.

The diagnosis here was made quite clear by the rapidity of the onset; the intense, localized pain slowly subsiding; the absence of marked pain in the limbs; the absence of fever at the onset; the absence of cerebral disturbance; by the early occurrence of anesthesia extending around the body and terminating about on a level with the fifth dorsal vertebra, in a very narrow line, above which there was no disorder of either motion or sensation.

Thus, it will be noticed, there were present many of the signs diagnostic of spinal hemorrhage, as well as others common both to it and to hematorrhachis, myelitis, and other diseases of the cord.

The differentiation was made from spinal tumor, aneurism, bone-disease, and inflammatory conditions of the cord resulting in paraplegia, by the suddenness with which the decided symptoms came on, while the condition differed from cerebral hemorrhage in the patient's undisturbed consciousness and speech. Embolus was also thought of as capable of producing some of the sudden symptoms, but this was excluded on the ground that it would hardly cause such complete paralysis.

Spinal meningeal hemorrhage remained to be excluded, and this was done because the sphincters of the bladder and rectum were so early affected; the pain was not marked in the limbs, and death very quickly ensued.

At the autopsy, careful examination of the cord showed an appearance of bulging just above the level of the fourth dorsal vertebra. Dissection at this point revealed a darkish-red clot, about the size of an almond, lying almost wholly in the gray matter. The parts of the cord immediately adjacent were somewhat softened, and were found by microscopic examination to be somewhat congested. Beyond this nothing abnormal was found.

As to the cause of the hemorrhage in this case, it is not easy to say, as the patient's history was negative concerning those conditions that are known to predispose to spinal hemorrhage, such as blows or traumatic injuries of the back, excessive fatigue, undue venereal indulgence, disease of the vertebra, and, rarely, the toxic influence of strychnine and the secondary effects of tetanus.

A remarkable case due to sudden congestion at the

menstrual period is reported by Goldammer in *Virchow's Archiv* for January, 1876.

The termination of this and of almost every other case of hemorrhage into the substance of the cord seems to expose to some doubt the correctness of the diagnosis in many of the cases reported as having recovered.

Many cases in which marked improvement takes place in a month or two, are doubtless cases of meningeal hemorrhage and not hemorrhage into the substance of the cord.

There are, however, well-authenticated cases of complete recovery following hemorrhage into the substance of the cord, among the most interesting of which is one caused by a blow upon the back, reported in 1867 in a monograph on the subject by Dr. John Ashhurst, and another observed by Cruveilhier.

PAGENSTECHER'S OPERATION FOR ENTROPION AND DISTICHIASIS, ILLUSTRATED BY TWO CASES.

BY HOWARD F. HANSELL, M.D.,
CHIEF OF EYE CLINIC OF JEFFERSON MEDICAL COLLEGE HOSPITAL.

IN Von Graefe's *Archiv für Ophthalmologie*, vol. xxxvi, pt. iv, is a description of Pagenstecher's modification of Hotz's operation for the cure of entropion and distichiasis, with the report of seventy successful cases and no relapse after five or six years. The writer, Dr. Otto Scheffels, expressed himself unqualifiedly in praise of the procedure and cordially recommended it. It is well known that many operations for the relief of this distressing affection have been devised, and none has proved more than moderately successful. The inverted and distorted eyelashes are found almost exclusively in old cases of granular lids. Granular conjunctivitis, or trachoma, should be regarded as a malignant disease, and frequently fatal to sight from loss of transparency and uncorrectable alteration in curvature of the cornea. These defects are caused in the first instance by the friction of the roughened lid, and later of the deformed cilia, distorted from their proper direction, over the smooth epithelial surface. The conjunctiva is shrunken and atrophied. The tarsal cartilage is thus more or less abnormally curved, and partial ptosis usually follows.

Pagenstecher's operation consists of the following steps: An indentation is made in the skin in the middle of the lid, one-half mm. below the tarsal border, in order to mark the exact site of the subsequent cut. The lid-forceps is next adjusted, the greatest care being exercised that the conjunctiva and blade are smoothly and exactly in contact. An incision is now made, commencing at the indentation and carried down to the cartilage, extending transversely to the right and left in its entire width. The upper half of the cartilage is exposed by freeing it from overlying muscle and fascia, carefully pushing those fibers above the cut upward and backward, and those below downward. The placing of the sutures is the final step. This should be carried out with the greatest nicety, since the success of the operation depends upon restoring the tendon of the levator palpebræ to its former position and attachment, from which it had become dislodged by the paralyzed fibers of the orbicularis. A curved needle, armed with moderately thick silk thread, is entered first in the center of the pad of muscle and skin, 2 mm. above the ciliary border, passed through the pad out into the cut, through the upper border of the tarsus and through the tendon of the levator, which has been grasped by a forcible thrust of the forceps held in the operator's left hand, and brought forward. Two other sutures are inserted in a similar manner, one on either side of and equidistant from the first. All are firmly tied. The divided integument is left open and allowed to heal by granulation. In four or five days the threads are removed.

CASE I.—F. G., thirty-one years of age, was the subject of granular lids for many years. Both upper lids had been unsuccessfully operated on in two clinics in Germany, for entropion and distichiasis. At the time of her first visit, V = R. $\frac{20}{CC}$, L. $\frac{5}{CC}$; the conjunctivæ were shrunken, the corneæ opaque. The left eye I considered nearly hopeless from dense opacity and commencing staphyloma. The right eye was the seat of severe pain from the constant irritation from the inverted lashes. The patient was obliged to remain in her room three days in every week, on account of pain and photophobia. A few weeks' treatment by depilation, atropine, etc., was of no permanent benefit. In December, 1890, the operation as described, was performed, the patient making a good recovery in a few days. Relief followed at once, and upon the occasion of her last visit, V in R. had improved to $\frac{20}{XL}$, and in L., in which an iridectomy was done, to $\frac{20}{CC}$. The eyelashes have attained their normal length, curve, and direction, and not one has since been extracted.

CASE II.—M. S., seventy years old, had granular lids of thirty years' duration, causing severe entropion, unrelieved by previous operations. The R. cornea was opaque and perforated by extensive ulceration. The L. was densely opaque and vascular. V = R., 0; L., light-perception. Pagenstecher's operation was performed on the L. in April, 1891. The patient was seen frequently during the summer, and there was no return of the entropion. V commenced to improve soon after the operation, continuing up to the time of her last visit, when it equalled $\frac{20}{CC}$, surely a remarkable result when it is considered that this eye had been of no service to her for many years.

I am aware that two cases are not sufficient to establish the invariable utility of any new surgical procedure, and that the lapse of time after the operations until this report would be held by many as insufficiently long to permit of a conclusive test. These cases must be regarded as simply confirmatory of Pagenstecher's good results, and not introductory of a new operation. It should be remembered, however, that they were extreme cases. Each had been the subject of previous operations that not only had not cured the disease but rendered later operations more difficult of performance and with less prospects of success. The results obtained were eminently satisfactory, and convincing to me, at least, that the procedure is founded upon proper principles and will obtain the first place among the methods devised for the relief of entropion and distichiasis.

SCARLATINA SINE EXANTHEMATE.

BY W. R. LEE, M.D.,
OF BARNESTON, NEB.

MEIGS and Pepper, in their work on *Diseases of Children* (seventh edition, 1883, p. 805), say: "It is impossible to distinguish scarlatina from the other eruptive fevers by the symptoms which precede the eruption. The only signs upon which a diagnosis at that time might be grounded are great frequency of pulse, which is characteristic of this disease, some soreness or redness of the fauces, and the prevalence of the disease in the community. But these are all exceedingly fallacious, and the physician should be content to wait for the eruption before he ventures to speak with certainty. After the eruption has come out, it can scarcely be mistaken for anything else, except it be roseola."

I shall not take issue with the statement quoted, but when one encounters a disease that presents all of the symptoms of scarlatina, *except the characteristic rash*, the situation becomes an embarrassing one. Surely, no one would hesitate to make a diagnosis of typhoid fever in a case in which all of the symptoms were present excepting the eruption. I append herewith a series of observations that cannot be without interest.

On December 1st I was called to see a girl seven years old, whom I found in light, restless sleep, with twitching of the muscles of the extremities. The pulse was 140 and became accelerated as she awoke. The temperature was 101.8° F. The tongue was covered with a thin, moist, white coating, except for a quarter of an inch at the edges, which were red and slightly swollen; scattered over the white surface, within a quarter of an inch of one another, were small, red, swollen points that gave the tongue a characteristic "strawberry" appearance. The throat, including the tonsils, arches, uvula, and, to some extent, the posterior wall of the pharynx, was swollen. Pain in the throat was only complained of in swallowing solid food. There was slight tenderness of the submaxillary glands. The appetite was impaired, but there was annoying thirst.

The history given by the mother was that the child was well until called from her play to supper, when she ate a light meal, and became apparently very ill at eight o'clock, an hour after which I saw her. Suspecting scarlatina, I gave precautionary instructions awaiting the development of the rash. A few points of redness appeared about the neck on the morning of the second day, but not enough to be characteristic.

On December 12th I saw Mrs. F., who presented phenomena similar to those observed in the preceding case, except that there was no glandular enlargement.

Between December 12th and January 15th I saw sixteen cases (five in adults and eleven in children) presenting similar symptoms, varying only in minor points.

In five of the cases, the glands were neither swollen nor tender. Three complained of soreness of the throat. In two children, vomiting was added to the nervous symptoms. In two of the adults, nervous phenomena were absent.

In all of the children, the pulse frequently ranged between 140 and 148; in one of the adults, it reached 140; in the others, it was between 130 and 134. In all of the cases the temperature was between 101.8° and 102 4° F.

In none of the cases, excepting the first two, was there anything that even resembled the rash of scarlatina.

I was forced to make a diagnosis of mild scarlatina "by exclusion," the verification of which has in some measure been made by the sequelæ.

In one child diarrhea appeared early in the second week. From the knowledge of most careful nursing in the case, I feel confident in considering the diarrhea as a sequel of the previous disease.

In two cases troublesome bronchitis appeared after the more active febrile symptoms of invasion had disappeared.

In two cases, after careless exposure, the swelling of the submaxillary glands returned, with slight elevation of temperature and acceleration of pulse.

In two cases desquamation took place, not extensively, but indubitably.

One of the adults, Mrs. C., on December 20th gave birth to a girl baby; the labor lasted seven hours, and for four days convalescence progressed without a complication. On the morning of the fifth day I found the woman presenting the train of symptoms and signs described, and, in addition, sore-throat, repeated swelling of the submaxillary glands, edema of the feet and legs, and ultimately a clearly defined attack of puerperal fever with localized peritonitis.

My medical colleagues do not concur in my diagnosis, in support of the correctness of which I present the following reasons:

The epidemic character of the disease: eighteen cases occurred in my own practice and there were four others of which I have information, in a community numbering not over five hundred souls in all.

Its contagious character: the disease ran through three families, and in four of the cases, in as many different families, it was possible to trace contact with the families in which the disease was prevalent.

The unusual similarity of the symptoms in all of the cases, presenting so many of the lesions of scarlatina, notwithstanding the absence of the rash.

The corroborative evidence found in the sequelæ.

MEDICAL PROGRESS.

Secondary Miliary Tuberculous Arthritis. — NICAISE (*Revue de Chirurgie*, 1891, No. 12, p. 1115) has recorded the case of a man fifty-six years old, whose health had been failing for about a year. Pains in the lower extremities had compelled him to take to his bed. Shortly after, the pain localized itself at the right knee, which soon became tumid; fluid collected in the joint. Movement at the knee developed crepitus. The thigh was atrophied. The second phalanx of the right ring-finger presented evidences of a past osteitis. Nothing abnormal was detected in the lungs; there was neither cough nor expectoration. Fungous arthritis being diagnosticated, the extremity was immobilized in a fenestrated silicate dressing, and vesicants and pressure applied to the joint, in conjunction with the administration of cod-liver oil and tonics. The condition of the knee improved, but the general condition of the patient, however, failed to participate in the improvement. On the contrary, the man lost appetite, and diminished in weight;

abdominal pains developed, without diarrhea; irregular cough set in, without expectoration; some moist râles could be heard in the left lung. Cerebral symptoms and elevation of temperature appeared. Progressive aggravation of the symptoms was followed by death. At the autopsy, only the lungs and the knee were examined. Both lungs contained many confluent miliary tuberculous granulations, especially at the apices, with no tendency to softening or cavitation or suppuration. The tissues of the knee-joint were thickened. The cavity of the joint contained an excess of fluid. The synovial membrane was the seat of numerous miliary granulations. The cartilages were softened and undergoing destruction. In the anterior wall of the articulation was a small caseous mass. In the tibia, at a point corresponding with the situation of this mass, were the evidences of a fungous osteitis. Miliary granulations were also found in the medulla of the femur. It is thought that the primary lesion was a simple fungous arthritis, to which subsequently a general tuberculosis was superadded.

Rupture of an Aortic Valve from Physical Exertion.—TRETZEL (*Berliner klin. Wochenschrift*, 1891, No. 44, p. 1073) has recorded the case of a large, muscular, hearty man, forty-one years old, who, while pushing a heavy cart, felt a severe pain in the chest. In the course of the day both the man and his wife observed a purring sound that emanated from the man's chest, and that occurred with the regularity of the pulse. Except for oppression of the chest and disturbance of sleep, the general condition was unaffected. On examination, a murmur could be heard at a distance of two or three yards from the patient, and it was observed that the sound was produced subsequently to the occurrence of the apex-beat. On palpation of the precordium, a tremor could be felt. Pulsation was detected in the epigastric region, in the carotids, and in the peripheral vessels. The area of cardiac percussion-dulness was already increased. On auscultation, a loud diastolic murmur was heard at and to the right of mid-sternum. A diagnosis of aortic insufficiency, from rupture of a valve leaflet, was made. The patient was lost sight of for two years, when he was found cyanotic and anasarcous. The heart had become enormously enlarged. Its action was frequent and feeble. The diastolic murmur was not as loud as it had been at first, and could no longer be heard at a distance from the chest. While under observation, the patient died suddenly. At the autopsy the heart was found to be immensely dilated and hypertrophied. The first part of the aorta was dilated. The aortic orifice was incompetent. The right leaflet at its anterior portion was torn from its attachment, and floated free in the opening. A linear cicatrix occupied the site of attachment of the valve. The remaining valves and orifices were normal.

The Toxicity of the Urine in Diseases of the Liver.—From a study of one hundred cases, SURMONT (*La Semaine Mèdicale*, 1892, No. 4, p. 25) has found that the toxicity of the urine undergoes changes in connection with diseases of the liver. It is augmented in atrophic alcoholic cirrhosis, in tuberculosis of the liver, in extensive and nodular carcinoma, in some forms of obstinate icterus, and sometimes in hypertrophic biliary cirrhosis. It remains normal or is diminished in hypertrophic alcoholic cirrhosis, in obstructive disease of the heart, and in certain periods in hypertrophic biliary cirrhosis. In infectious jaundice, catarrhal or grave, the toxicity of the urine remains normal or is diminished at the height of the attack, but increases with its decline. The toxicity of the urine remains normal or is augmented as the hepatic cells are normal or altered, either in structure or in function. When the toxicity of the urine is augmented a milk diet and intestinal antisepsis are rigorously indicated.

Carcinoma of the Stomach.—As a result of a study made at the clinic of Lépine, at Lyons, MOUISSET (*Revue de Mèdecine*, 1891, No. 10) has found that the blood of patients with carcinoma of the stomach suffers as decided a diminution in the proportion of hemoglobin as in the case of chlorosis. This knowledge constitutes a valuable point in differential diagnosis, especially between carcinoma of the stomach and pernicious anemia. In the former, the proportion of hemoglobin is decidedly diminished; in the latter, the proportion is normal or increased.

Of twelve hundred deaths from all causes, sixty-one were found to be due to carcinoma of the stomach, and in twelve of these pulmonary tuberculosis was found associated.

Lysol in the Treatment of Aural Affections.—HAUG (*Journal de Mèdecine de Paris*, iv, 2, 1892, p. 13) recommends irrigation with a centesimal solution of lysol in the treatment of otorrhea. In case of coëxisting inflammation of the meatus and tympanic membrane, the irrigation is preceded by instillation of few drops of a solution of forty-eight grains of cocaine hydrochlorate in a half-ounce each of distilled water and alcohol. In case of otomycosis several drops of a solution of twenty grains of lysol to an ounce of alcohol are introduced into the auditory meatus twice daily, and permitted to remain for ten minutes. As a dressing, gauze impregnated with a solution of from ten to twenty grains of lysol in half an once of distilled water and two drams each of glycerin and alcohol may be employed.

Cranial Auscultation.—RICHARDSON (*Asclepiad*, 1891, viii, 32) records several cases of vertigo and noises in the ear or cranium, alone or associated, in which, upon the application of the stethoscope to various parts of the head, murmurs could be heard, in some instances dependent upon valvular lesions of the heart, in others probably upon aneurism, and in still others probably upon roughening of the intima of the arteries. Local treatment is likely to do harm. The constitutional treatment will depend upon the underlying condition. The best sedative is a combination of dilute hydrobromic acid, from fifteen to twenty minims; infusion of digitalis, half a fluidounce; and distilled water, sufficient to make an ounce and a half as a dose.

A Case of Anthrax Cured by Excision and the Employment of Ipecacuanha.—DAVIES-COLLEY (*Lancet*, No. 3555, p. 872) has reported the case of a horse-slaughterer, in which, after a scratch upon the left side of the face, swelling and induration developed, involving the eye-

lids and the cheek, and extending to the subclavicular region. A slough formed, in the serum of which anthrax-bacilli were found. A disc of skin was excised from the focus of infection, and the wound was covered with powdered ipecacuanha. Five grains of ipecacuanha, with one-sixth of a grain of morphine, were administered every four hours. For three days the condition grew worse, but subsequently improvement set in and gradually progressed to recovery.

Movable Kidney and Hydronephrosis.—LUCAS (*British Medical Journal*, No. 1617, p. 1343) maintains that movable kidney is a condition that, during displacement, may, and often does, lead to hydronephrosis and subsequent destruction of the kidney, in consequence of twisting of the pedicle, or pressure of the organ upon the ureter. To avoid this danger, and to relieve the patient of pain, he recommends nephrorrhaphy. Even when hydronephrosis has become pronounced, relief may be afforded by nephrorrhaphy, and further degenerative change prevented. Three cases are reported, in two of which nephrorrhaphy was performed; in one, nephrectomy was performed; in one, operation was declined.

The Pathology of Paralysis Agitans.—BORGHERINI (*Rivist. sper. di Freniatria e Med. leg.*, 1891, vol. xvii, fasc. 1, 2) has reported a case of paralysis agitans, in which after death, on careful microscopic examination, an excessive formation of connective tissue was found in various parts of the cerebro-spinal nervous system, with pigmentation and atrophy of gray matter and ganglion cells. The walls of the capillaries were thickened, the lumen of the vessels was increased, and the perivascular lymph-spaces were dilated. In many places miliary aneurisms were present. The lesions are thus those of senile involution.—*La Médecine Moderne*, 1891, No. 43, p. 746.

The Suture of Nerves.—At a meeting of the Berlin Medical Society, GLUCK (*Deutsche med. Wochenschr.*, 1891, No. 46, p. 1273) presented a man twenty-two years of age who, following a punctured wound of the arm, developed complete radial palsy. Enlarging the wound, it was found that the musculo spiral nerve had been divided. The proximal and distal extremities were carefully sutured and the wound was closed. At the expiration of a month, electric treatment was instituted. At the expiration of five months, reactions of degeneration were still present, but power of movement was beginning to return. A favorable prognosis was expressed.

Fatal Hemorrhage from Scarification of the Conjunctiva.—SHIRLEY (*New York Medical Journal*, 1892, lv, 1, p. 15) has recorded the case of a mulatto infant, six weeks old, with hereditary syphilis, in which fatal hemorrhage followed scarification of the palpebral conjunctiva for purulent conjunctivitis. Hot water, ice, and styptics failing to restrain the hemorrhage, sutures were passed beneath the bleeding surfaces and the upper and lower lids were united. The hemorrhage was controlled, but the child died.

Cresol-iodide.—SZOLDRSKI (*Münchener med. Wochenschr.*, 1891, No. 43, p. 753) has employed local applications of cresol-iodide in various acute and chronic affections of the nares and larynx. While exerting no direct influence upon the pathological process, the agent proved specially useful in checking excessive secretion. It also acted beneficially when applied as a disinfectant after operations in the nares and larynx. Over iodoform cresol-iodide has the advantage of being inodorous.

Purpura of the Mucous Membrane of the Mouth, Pharynx, and Larynx.—AUDUBERT (*Annales de la Policlinique de Bordeaux*, 1891, No 5) has recorded the case of a man, fifty years old, with tuberculosis of the larynx and lungs, in the course of which purpuric spots appeared upon the uvula, the tongue, the gums, and in the larynx and pharynx, but nowhere upon the skin or in the nares.—*Wiener klin. Wochenschr.*, 1891, No. 43, p. 813.

The Treatment of Anthrax and Analogous Conditions.—By experiments upon animals and by clinical observations in man, NISSEN (*Deutsche med. Wochenschr.*, 1891, No. 53, p. 1425) has been able to demonstrate that the immediate application of an elastic ligature to the proximal side of a wound infected by anthrax, together with a thorough cauterization of the wound, will prevent the development of anthrax. Either procedure alone will not suffice. Nissen suggests the application of the principle to be deduced to the early treatment of other infections introduced through the medium of the lymphatic system.

Benzosol as a Substitute for Creasote.—To some tuberculous patients the odor and taste of creasote are extremely unpleasant, and in some the administration of the remedy in suitable doses gives rise to impairment of appetite and derangement of digestion. Guaiacol, the active constituent of creasote, is open to similar objections. The most recent substitute proposed consists of a combination of guaiacol and benzoic acid (the proportions are not stated), designated benzosol. HUGHES (*Deutsche med. Wochenschr.*, 1891, No. 53, p. 1435) has employed benzosol in a series of twenty cases of pulmonary tuberculosis, with highly gratifying results. Appetite returned, cough diminished, the subjective condition improved, and there was increase in weight. Benzosol is a white powder that may be administered thrice daily, after meals, in doses of three grains, made into troches, with the addition of a twelfth of a minim or more of oil of peppermint. For a week, three troches may be given daily; then for three weeks, six troches daily; for the next week, three troches daily; in the sixth week the administration is intermitted, to be recommenced in the seventh.

Tuberculosis in the Goat.—It has been maintained that goats possess immunity from tuberculosis. At a meeting of the French Academy of Medicine, COLIN reported the development of tuberculosis in a goat that had been inoculated with tuberculous tissue obtained from a cow. The goat died two months after the inoculation, presenting tuberculous involvement of the lymphatic glands and of the lungs.—*Deutsche med. Wochenschr.*, 1891, No. 53, p. 1436.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

DUTIES OF THE ELDER PRACTITIONER.

WITH his practice established, his position assured, or quite as much so as may be expected, what are the duties of the elder to the younger practitioner? The latter, by the fact of his coming, asserts his right to a place, and, in a certain sense, lays claim to a sharing of the work of the elder. Shall the claim be allowed by cordiality of reception, or be disallowed by secret opposition and neglect? It would seem that the question were needless, in view of the tradition of ethics that has long been the pride of our profession, and the large humanitarianism that, from the earliest times, has characterized the medical guild. Envy is an unworthy motive and especially so with physicians. The object of their life-work does not warrant such selfish indulgence. Whether willingly or unwillingly, whether sooner or later, the younger must take the place of the elder; better the passing of the torch by consent and good-will than by wresting and ill-will.

Instead of an individualism and struggle for personal place, it harmonizes with ideals of professional success to cultivate a desirable *esprit de corps*, or common unity. The work of the elders should be directed to preventing the entrance into the profession of the unworthy and unfitted, rather than embittering the lives of those allowed admission. Let the standard of medical education, the preliminary and final examinations, be made more stringent, and the lengths of college courses be increased, etc., so far as wished, but the theoretic right to practise as authorized by the conferred degree should be followed by the practical welcome from those longer in the work.

In the choice among many younger competitors the "practical welcome" should, of course, be conditioned upon character. When self-assertion and the outcropping of low ethical standards, incompetence, etc., are manifest, neglect is certainly justifiable. But when deference, capacity, and personal honor are evident in the younger men, the welcome should be clear and frank. What are a few of the prosaic and practical methods of effecting this welcome?

1. By encouraging the habit of frequent consultations in severe or puzzling cases of illness, and by lessening the obstacles in the way of such consultations. The proposal or possibility of these consultations is often shut out by the knowledge of the high fee of the consultant. Why should the charge be disproportionately higher in consultation cases than in others?

2. By summary and effective measures to stop the deplorable abuse of medical charity by rival hospitals and dispensaries. Efforts to this end apparently meet a horrible dead-wall of indifference on the part of older men. It is, indeed, they that usually keep up and increase the abuse. It is a crying injustice to the younger professional men. It must be stopped, both for the sake of the public and for the sake of the profession, being injurious alike to both. The remedy lies in the hands of the older members of the profession alone.

3. By making the bestowal of hospital and subordinate teaching positions sought by the younger dependent upon character and medical attainment, not upon scheming and "private pulls." Anyone that has once seen the inside wire-pullings, the filthiness of medical politics displayed in a scramble for place, realizes how nearly the methods of the ward politician are adopted in the allotment of these official positions. It is quite certain that often the worst men succeed, not the best. The most brazen impudence and flashy capacities make the most noise; the modest and self-respecting shrink from the self-advertisement and the importunities of friends that the schemer delights in, and the

schemer is preferred. Boards of trustees of colleges or hospitals should be guided by the wisdom of elder physicians and should reject the wire-puller, if for no other reason than that he is a politician. Character and honest competitive examination should go for more than "influence." Capacity is not usually associated with conceit, and when the man seeks the office with egotistic pertinacity it is, *per se*, pretty sure proof that he is unworthy. Let the office seek the man!

4. By the formation of local medical societies and guiding them toward scientific usefulness, and by upholding ethical standards and practices. Of prime importance and great service would be the society medical library, where great works of reference, a wide variety of medical journals, etc., could supplement the private library. How rare is this in any but the largest cities, and yet it is precisely the country and village practitioner that most needs such helps. The difficulty experienced in getting together men so busy and so scattered should be overcome by unwearying endeavor, supported by the knowledge that association, essay-reading, reports of cases, etc., the friction of mind upon mind, leads to professional results doubly repaying the trouble. Such active, local, suburban societies would help further the very desirable but sadly-neglected practice of lecture-giving by invited visiting physicians and specialists. Why not apply "university extension" to medicine, and make an organized system of addresses a part of the year's work of county medical societies? But perhaps the greatest good of such societies is to prevent the ethical degradation that has to be guarded against with jealous care. It is the elder men that having learned by tradition and experience the fatuity and falsity of the maxim, *Medicine is a business*, should pass the tradition on and down to the younger, who are often sadly prone to accept the new creed. An illustration has lately occurred in a small neighboring city. A quack, whose patient's ingravescence was landing him in an unenviable position, wished the moral support of a consultation, and secured the help of a young physician solicitous of practice and indifferent to the code. The discipline of the harmonious medical society, rallied by the old president, taught the boy a needed and lasting lesson.

5. Against the itch of advertising in the lay press the older men should exercise the most stringent guard. Firstly, as to themselves, or else they cannot blame the younger. They well know the means whereby the "great cure" and the "great operation" get into the papers. It is rarely without authorization, as it is the experience of those who do not wish to be quoted that reporters do not go against the expressed will of a physician. Sometimes the elder lets the unauthorized puff go, from indifference or secret love of it; and then the younger, "taking fire" from bad example, steps clean over the traces, gives the ubiquitous reporter *carte blanche*, and the elder cannot then control the younger. His hands are palsied by his secret sin.

6. It is the same story with the wretched habit of signing commendatory notices of certain drug, food, or proprietary preparations. When the dishonest younger man goes into service, receives actual pay for his labor in behalf of some pharmaceutical firm, he has the cutting excuse that every nostrum advertisement he receives contains the praises of a thousand old physicians, perhaps wheedled out of them by the shrewd agent, but possibly given only for value received. Let there be no copartnerships, secret or open, of medical men with manufacturing tradesmen!

In these and many other ways the older men can advance the interests of medical science, fraternize and unify the members into a compact body more powerful for self-help and for public beneficence. It is too prevalent a habit for the elders to retire, either in weariness or in indifference, from the actual work just indicated, with the thought: "I am secure, let the youngsters work it out as they please." But they know in their hearts that it is not right—that it is shirking the most obvious of obligations.

THE CURABILITY OF TUBERCULOSIS.

THE day has passed when the thinking and observant longer have any doubt as to the curability of tuberculosis. It seems almost superfluous to dwell upon the proposition, but it may serve a useful purpose to call the attention of the busy medical practitioner and of the community to its truth and importance. Many a battle has been gained that otherwise might have been lost, when discipline has supplanted demoralization. If the patient can be made to believe that the disease with which he suffers is curable, the therapeutist will find his task the easier; and if the patient can be made to realize that recovery is the more likely the earlier

treatment is begun, the prognosis becomes still more hopeful. In this connection the *Seventh Annual Report of the Adirondack Cottage Sanitarium* is especially valuable. Of seventy-seven patients dismissed, fourteen were apparently cured; in twenty-three the disease was arrested; and twenty-two cases were improved. Can more convincing argument be presented?

It would be tiresome here to detail the treatment of tuberculosis. Each case is a law unto itself. With a proper regard for the etiologic part played by microörganisms in the drama of disease, let us not mistake the cause for the effect—the organism is not the disease. Living as we do in the midst of myriads of disease-producing agencies, existence would be but a series of infections were it not for some kind barrier placed between us and disease. Something more than seed is necessary for vegetable development: not less important is soil. So in the treatment as in the prophylaxis of tuberculosis, it is the constitution and not the germ that requires attention. The principles that should govern the treatment in any case are dependent upon the maintenance of functional activity. The quality of the blood should be improved by good, nutritious food discriminatively administered, by the removal of excrementitious products by the emunctories—skin, kidneys, lungs, bowels—and a proper equilibrium be established between waste and repair. When indicated, the surgical axiom of removal of an accessible source of irritation, when removal is not attended with greater dangers than non-interference, will find application.

MEDICAL DOGMAS.

IT is too much to expect that superstition will ever be eradicated from our common life. We scoff at the delusions of our ancestors, failing to see our own illogicalities. Medicine is not entirely exempt from the common failing. It was a long time before we were willing to believe that the arteries did not contain air. Two centuries elapsed before the germ-theory of disease was accepted. It took many years to overcome the belief that malignant neoplasms depended upon the circulation of humors or noxæ in the blood. There are not a few that today maintain that valvular disease of the heart (especially mitral incompetency) and pulmonary tuberculosis do not coëxist; that carcinoma and pulmonary tuberculosis do not occur in the same person. There are many sources of error in such theories. The possibility of error is reduced to a minimum by objective study, by observation. Who that has looked has not seen associated the conditions that it has long been taught are not associated. There are few things of which one can say that they cannot be.

In a study of twelve hundred autopsies at the clinic of Lépine, at Lyon, MOUISSET (*Revue de Médecine*, 1891, No. 10) found that there were sixty-one cases of carcinoma of the stomach, in twelve of which pulmonary tuberculosis coëxisted. Such evidence constitutes a rebuke to dogmatism and prejudice. It could not be shaken by libraries of negative testimony. Can any argument be more conclusive?

THE NECESSITY OF STATE MEDICAL EXAMINATIONS.

THE salutary effects of State medical examinations are forcibly illustrated in the report of the Medical Examining Board of the State of Washington. Of thirty applications for authority to engage in the practice of medicine, fifteen were rejected. The questions asked were of such a nature that only the incompetent could fail of the requisite average. The report is but a repetition of like reports that have emanated from other States. As a result of restrictive medical legislation, not only is the number of successful applicants reduced, but the actual number of original applicants is also diminished. It is the imperative duty of the State to afford the community adequate protection from the devices and intrigues of quacks and adventurers, with whom reputable men and women cannot compete.

REVIEWS.

REPORT ON CHOLERA IN EUROPE AND INDIA. By EDWARD O. SHAKESPEARE, A.M., M.D., Ph.D., of Philadelphia, United States Commissioner. 4to. pp. xxv, 925. Washington: Government Printing Office, 1890.

THIS bulky volume, representing an enormous amount of labor and much patient research, gives the results of the investigations undertaken by Dr. Shakespeare in pursuance of the executive order of the President of the United States, which directed him "to proceed under the direction of the Secretary of State to Spain and such other countries of Europe where the cholera exists, and make investigation of the cause, progress, and proper prevention and cure of the said disease." Upon Dr. Shakespeare's arrival in Europe, early in 1885, pursuant to this commission, he found that the cholera was rapidly vanishing from that continent, and learned that

the field for most active observation was to be found in Palermo, the principal city of the island of Sicily. After equipping himself with a travelling laboratory, purchased in Berlin, and familiarizing himself in that city with the characteristics of the comma bacillus of Koch, he went to Palermo and began his work. After the epidemic was ended at Palermo he turned to Spain, gaining information relating to the ravages of the epidemic in Italy, traversed *en route*. He arrived in Barcelona early in January, 1886, and found that the cholera had virtually disappeared from the kingdom of Spain; but because of the great extent and severity of the Spanish epidemic of 1885, as well as on account of the very large number of so-called anti-choleraic inoculations which had been practised by Dr. Jaime Ferrán and his assistants, he was of the opinion that the course of the cholera in Spain presented the best opportunity of making as thorough a study of the disease as was in his power. He visited many towns in nearly every province of Spain where cholera had spread widely, endeavoring to obtain by personal contact with the inhabitants, of high and low station and intelligence, a fundamental knowledge of the circumstances of life, manners and customs, and hygienic conditions, general and individual, which might bear upon the manner of introduction and spread of cholera among them. Especial attention was given to the matter of water-supply and the disposition of household offal. In the round of this personal observation he encountered and spent some time in the midst of a quite severe epidemic, during the month of February, in the ancient walled town of Tarifa, on the northern shore of the Strait of Gibraltar. In addition, he obtained from official sources a careful analysis of numerous and important data concerning the epidemic and the hygienic conditions in upwards of five hundred cholera-stricken towns. Before receiving this, he had undertaken a similar investigation, the results of which were added to and analyzed with the above-mentioned official documents of the Spanish Government. He has also obtained and placed in his report official statistics and documents relating to the anti-choleraic inoculations in Spain. After leaving Spain in April, 1886, authority was requested and obtained to proceed to India, for the purpose of prosecuting researches in the native home of cholera. Serious illness, due to the prostrating influences of the summer climate, prevented him from entirely carrying out his purpose, but he was able to take some observations in the city and suburbs of Calcutta. The report contains 105 illustrations, most of which were made by the author himself; among them 40 photo-micrographs, all but 6 of them being made by Dr. Shakespeare, who was obliged to acquire the art of photography, because he could get no one to do this troublesome work. Numerous analytical charts and tables relating to cholera statistics have been incorporated. There is a full table of contents and a cross index, which will considerably facilitate reference. The work of foreign investigation, continuing one year, and the labor of supervision of the printing of the report, lasting four years, have all been entirely without pay for personal services, and the profession and the country certainly owe Dr. Shakespeare a debt of gratitude for his arduous, patient and successful labors.

The report is exhaustive: the course of the last widespread epidemic of cholera is traced in detail, and, in addition, we have comparative statistics of previous epidemics in a number of the localities studied.

The last epidemic of cholera in Europe cost France 15,000 inhabitants; Spain, 180,000 inhabitants; Austria-Hungary, 4000 inhabitants; Italy, about 50,000 inhabitants; Malta, 500 inhabitants—the sum total of mortality being approximately 250,000 human beings. Estimated from a merely material point of view, this shows a sum-total of about 400,000,000 francs of value destroyed; and still greater losses resulting from the damage caused by the disease through idleness, interference with commerce and navigation, interruption of business, and the like, would increase the sum-total of the loss occasioned by the cholera to about a billion of francs in three or four years.

The hygienic surroundings, sanitary conditions, and other circumstances bearing upon the rooting of cholera in various places, whither its seeds are carried, have been carefully studied, and especial attention paid to elucidating the method of its transmission from place to place.

This subject occupies 370 pages. Some seventy-odd pages are next devoted to the "Topography and Demography of British East India in Relation to Cholera."

Bacteriologic investigations and literature occupy more than two hundred of the closely printed quarto pages. A chapter is given to the etiology of cholera and its differential diagnosis from malaria. Immunity and preventive inoculations are each given a chapter. Another chapter deals with measures of prevention, general and individual, and the eighth and last chapter summarizes the etiology and pathology, diagnosis, prognosis, and treatment of the disease.

Dr. Shakespeare's experience, together with his study of the literature of the subject, forces him to admit that the claim made by Koch must be regarded as established, namely, that the presence of Koch's comma bacillus in the alvine evacuations or the intestinal contents or vomit of an individual suffering with a suspicious attack, furnishes a ready, safe, and reliable means of diagnosis of Asiatic cholera. He also confirms in every particular the pathogenic power of the comma bacillus affirmed by Koch. He believes that the exceedingly few adverse reports, when not invalidated by retraction of the authors upon subsequent experimentation, can be explained by the fact that the comma bacillus in artificial culture often rapidly loses its pathogenic power. Dr. Shakespeare is also inclined to admit the claims of Ferrán as to the preventive value of inoculations with a special culture of the comma bacillus, and he believes this to be a complementary proof of the correctness of the claims of Koch, that this comma bacillus is the specific active cause of Asiatic cholera.

Apropos of the Ferrán inoculations, Dr. Shakespeare says that having received unfavorable impressions of Ferrán from what had been published concerning him by the medical and secular press throughout the world, and having been advised by numerous physicians and investigators in London and Berlin, for whose opinions he entertained the highest respect, that a personal investigation of the subject was now beneath the dignity of serious scientific consideration, he was little disposed,

except by a sense of duty, to give himself any trouble in the matter. But besides the impulse of duty, he was stimulated to look into the character and accomplishments of Ferrán and the value of his work by a visitor who called on the morning of his arrival in the city of Valencia. This gentleman was a certain Dr. Jelly, a man apparently of some seventy years of age, who appeared to be strongly convinced of his own consequence. He desired to set Dr. Shakespeare right on the Ferrán question before the latter had wasted any time in personal investigation relating thereto. This gentleman having been the author of a mass of unfavorable correspondence concerning Ferrán in the British medical journals, Dr. Shakespeare was now able to judge for himself of the importance and reliability which should be attributed to those articles, and in the course of the interview soon became convinced by the manner and language of Dr. Jelly, that not only was this gentleman perfectly incompetent to furnish any judicious opinion concerning questions involving an intimate knowledge of modern ideas relating to general pathology or to microscopical investigations, but also that what opinions he might form were likely to be influenced and warped by the most bitter prejudice. The interview convinced him that while he had the opportunity he should personally go to the bottom of the whole Ferrán question, if possible. Quite different was the impression made upon him by Dr. Ferrán. His laboratory was certainly unpretentious, but it had a good modern microscope, and Dr. Ferrán himself was found to be perfectly competent in the question of technique. Honesty and a regard for fair-dealing require the author to say that if anywhere in Europe there are more beautifully stained microscopic preparations than those made by Dr. Ferrán, he has never seen them. Prepared to find the characteristics of a charlatan in the man himself, he found him to be a quiet, reserved, courteous, intelligent, and generally well-informed physician. The impressions formed of his theoretic knowledge of bacteria and of the modern methods of research in the field of natural history compared very favorably with those of most of the leading bacteriologists with whom the author came in contact. He therefore left Tortosa with a very different opinion of the characteristics of Dr. Ferrán from that he had entertained when entering that city.

Dr. Shakespeare cites data from official statistics that have been collected and published since the visit to Spain of the French Commission, which made an adverse report upon Ferrán's procedure. These statistics are signed, in the first place, by the physicians of the locality; in the next place, by the judge of the municipal court; sometimes, also, by the president-judge of the judicial district, by the parochial priest, and by the mayor of the municipality, whose signatures and seals are attested by an authorized notary public. From these statistics it appears that in the Province of Valencia there were, among the villages, inhabited by a population of 50,000, 62 attacks per thousand and 31 deaths per thousand, a mortality of 50 per cent. of those attacked. In twenty-two towns in which inoculation was practised, the inhabitants were divided as follows: 104,561 not inoculated, 30,491 inoculated. Of the latter, there were 387 attacks of cholera, or 12 per cent., and 104 deaths, or 3 per cent., the mortality of those attacked being 27 per cent. Of the former, there were 8406 attacks, or 79 per cent., and 3512 deaths, or 33 per cent., being a mortality of those attacked of 43 per cent. It appears, therefore, that among the population of villages in which anti-choleraic inoculations had been more or less extensively made, the liability of the inoculated to attacks of cholera was 6.06 times less than that of the non-inoculated, whilst the liability of the inoculated to death by cholera was 9.87 times less than that of the non-inoculated. Still another result of the preventive inoculations apparently shown by these statistics, is a marked shortening of the course of the epidemic after a large percentage of the inhabitants had been inoculated. Dr. Shakespeare believes, therefore, that the method of Ferrán, besides giving the subject inoculated considerable immunity from attack and death, furnishes a means of bringing an epidemic rapidly to an end. "The cholera vaccine" is nothing more than a pure culture in bouillon of the comma bacillus.

Dr. Shakespeare is an ardent advocate of efficient quarantine by land and by sea. Admitting the frequent insufficiency of quarantine, he insists that there is a great difference between insufficency and uselessness. In addition, he advises isolation of the quarantined sick in groups of patients. He considers the present methods of independent quarantine, provided and regulated by seaboard States or cities, as especially defective and insufficient for the exclusion from the United States of the diseases against which quarantine is directed; that "it is impossible adequately to protect the public health of the country against the importation of epidemic diseases by independent local maritime quarantine establishments," and that, therefore, a national system of maritime quarantine is necessary. Concerning general measures of prevention, he advocates speedy isolation of the sick, absolute and rapid destruction of the infectious agents of the disease, not only in the dejecta and vomit, but also in clothing, bedding, and in or upon whatever it lies and finds a resting-place.

Convalescents should remain isolated from the healthy so long as their stools contain any of the infectious agent, say from ten to fourteen days; and before mingling again with the well, they should be thoroughly washed and cleansed in a disinfecting bath, and afterward be clothed from the skin outward with perfectly clean vestments that cannot possibly contain any of the infectious material. Proper precautions should be taken as to the disposal of the dead, and those handling the sick or the dead should be careful to disinfect their hands and clothing at once. Careful directions are given for the management of quarantine stations, and the measures of prevention there to be carried out.

The subject of prophylaxis, individual and general, is elaborately studied. Differential diagnosis is summarily treated. The treatment advocated is that found in the approved text-books, with the addition of "hypodermoclysis" and "enteroclysis;" the former being carried out with a solution composed of pure sodium chloride, eighty grams, sodium carbonate, six grams, in two liters of boiled water, of which from one to two-and-a-half liters are injected each time; the latter with tannin and laudanum. Both of these methods were introduced by Cantani, of Naples, and used with great confidence by him and other Italian physicians. Dr. Shakespeare

is seemingly unaware that Cantani was long antedated by Benjamin Ward Richardson, who saved many patients from choleraic collapse by injections of hot water or hot milk into the peritoneal sac, and in one fatal case produced repeated temporary revival by subcutaneous injection of a warm solution of sodium chloride.

The only and very mild fault-finding we have to make concerning Dr. Shakespeare's report is that it might possibly have been better arranged for consecutive study; but with the vast amount of material that the author had to manipulate, he has certainly done wonderfully well, even in this respect.

A SYSTEM OF PRACTICAL THERAPEUTICS. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Assisted by WALTER CHRYSTIE, M.D., late Physician to St. Clement's Hospital, and Instructor in Physical Diagnosis in the University of Pennsylvania. Vol. I. General Therapeutic Considerations; Prescription-writing; Remedial Measures other than Drugs; Preventive Medicine; Diathetic Diseases and Diseases of Nutrition. With illustrations. 8vo, pp. 1052. Philadelphia: Lea Brothers & Co., 1891.

ANY doubt as to the necessity for a new work on therapeutics will be dissipated by a reference to this system, which will create for itself a permanent position in medical literature. Here are brought together the deliberate opinions and the mature results of the experience of men skilled in their respective departments, while the literature of the world has been liberally drawn upon. The limits of the ordinary review will only permit of passing reference to the different articles, as each in itself is a monograph, while several constitute treatises. Under "General Therapeutic Considerations," Horatio C. Wood outlines with characteristic precision and force the principles of therapeusis, with the indications for their application. In "Prescription-writing and the Combination of Drugs," Joseph P. Remington presents a good deal of useful information that will be gratefully appreciated by the careful and intelligent practitioner. In the section on "Remedial Measures Other than Drugs," A. D. Rockwell considers "Electro-therapeutics" from a practical standpoint, indicating its applications to diseases of the nervous system, to gynecology, and to obstetrics. John K. Mitchell presents as an authoritative statement of the most recent views of Dr. S. Weir Mitchell, and of the latest developments in this method of treatment, an article on "Rest-cure for Neurasthenia and Hysteria." Benjamin Lee contributes a thorough and exhaustive paper on "Swedish Movements and Massage." Edward Mussey Hartwell fully considers the subject of "General Exercise." S. Edwin Solly discusses the various aspects of "Climate"; and Simon Baruch devotes some eighty pages to a masterly consideration of the subjects of "Hydrotheraphy" and "Mineral Springs." A gratifying feature of many, if not of most of the articles, is the consideration given to the prophylaxis of disease. There is, besides, a division of the work devoted to "Preventive Medicine," which includes articles on "General Sanitation," by Henry B. Baker; on "Disinfection," by George M. Sternberg.; on "Antisepsis and Asepsis," by J. William White; and on "Nutrition and Foods, including the Treatment of Obesity and Leanness," by J. Burney Yeo. The subject of "Diathetic Diseases and Diseases of Nutrition" is opened by a scholarly and exhaustive paper of more than two hundred pages on "Tuberculosis," by Solomon Solis-Cohen; in succession follow "Scrofulosis and Rhachitis," by Walter Chrystie; "Acute and Chronic Articular Rheumatism, Rheumatoid Arthritis, and Gout," by James Stewart; "Scurvy," by John B. Hamilton; and "Diabetes Mellitus," by Frederick A. Packard. An index of sixteen pages concludes the volume of 1052 pages.

The work reflects great credit upon contributors, editors, and publishers. It is a monument to, as it is a record of, scientific therapeutics. It should be in the library of every progressive practitioner of medicine.

A TEXT-BOOK OF HUMAN PHYSIOLOGY, INCLUDING HISTOLOGY AND MICROSCOPICAL ANATOMY, WITH SPECIAL REFERENCE TO THE REQUIREMENTS OF PRACTICAL MEDICINE. By L. LANDOIS, M.D., Professor of Physiology and Director of the Physiological Institute, University of Greifswald. Translated from the seventh German edition. With additions by WILLIAM STIRLING, M.D., Sc.D., Blackenbury Professor of Physiology and Histology in Owens College, and Professor in the Victoria University, Manchester. With 845 illustrations, 34 in colors. Fourth edition. Philadelphia: P. Blakiston, Son & Co., 1891.

WHEN the first American edition of this text-book was published, it was predicted that it would have a large sale, not only among students of physiology, on account of its completeness as a work of physiology, but also among practitioners of medicine and surgery, on account of the numerous applications of physiology to pathology and clinical medicine. The instant and continued success that the work achieved is the best possible proof that it possesses merits far beyond the usual text-books. The first German edition appeared in 1880, the seventh in 1890; the first English edition appeared in 1885, the fourth in 1891. The rapid publication of successive editions is an indication of the favor with which it has been received by the profession of both German and English-speaking people.

With each new edition, author and English translator have endeavored to maintain a high standard of usefulness by incorporating all of the recent advances in physiologic science that appear to have permanent value, as well as facts of clinical medicine, pathology, and experimental therapeutics which reveal the connection and interdependence of all vital processes. There is no similar work in the English language that contains such an inexhaustible fund of useful information pertaining to physiology and the allied sciences. The physician and student will here find an answer to almost every question that may arise from day to day in the course of his investigations. Indeed, no working library can be said to be complete without the book.

Physiologic and chemic methods are briefly and clearly described, and the results obtained are presented in a concise and readable form. The illustrations, 845 in number, are striking and apposite, and materially assist in the elucidation of the text.

CORRESPONDENCE.

TREATMENT OF PNEUMONIA.

To the Editor of THE MEDICAL NEWS,

SIR: Many deaths have occurred from pneumonia as a sequel of influenza or *la grippe* in all parts of the civilized world, independently of geographical position or hygienic surroundings, killing alike the prince in his palace and the pauper in his hovel, and apparently in many cases not amenable to recognized rules of treatment. In view of this fact one is inclined to ask whether the opinion of Dr. Coupland, of London, in a paper on "Pneumonia" (*British Medical Journal*), in which, advocating expectancy, he states that "as regards the drug treatment of pneumonia nothing can be done," is, after all, the best advice. In spite of the great weight that must attach to the opinion of so experienced a physician, I would ask if in excluding drugs one can be said to render all the assistance possible to Nature in helping her to work out a cure. For example, when a great portion of the lung is involved, with dyspnea and cyanosis, can nothing be done? Let us consider the causes of these symptoms, which are of such grave import: there is an effusion in the pulmonary tract from the liquefaction of the blood, which causes a nonaëration of the blood; and there is also great extravasation of leucocytes, which characterizes the state of the lung-exudation when resolution has failed to take place. It is under such conditions as these that the preparations of iron are of peculiar benefit. For some unaccountable reason there seems to have been a prejudice in the minds of many practitioners against the use of iron in chest-affections, but I feel satisfied that those that try the iron-treatment in pneumonia will have no cause to regret so doing, and those that have already used it, if their experience has been like mine, will certainly continue its use. For five years I have made a practice of treating cases of pneumonia, when symptoms such as those quoted appeared, with fifteen-minim doses of the liquor ferri perchloridi, and the same amount of liq. ammon. acetatis, given every three hours. Early and brisk counter-irritation is undoubtedly one of the most important points of treatment.

The question that becomes one of practical import now is whether cases of influenza showing a tendency to chest-complications would not be best treated with some preparation of iron from the outset and thus possibly avoid the pathologic degeneration in the lung-tissue that has unfortunately been accompanied with such fatal results. It is at least a matter well worthy of the most careful consideration of the profession. It is to be hoped that some of your readers will contribute their opinions on the subject. Respectfully yours,

A. H. FRASER,
Licentiate Royal College of Physicians, Edin.
HARPER, KANSAS.

IS URIC ACID A PRIME OR SOLE FACTOR IN THE CAUSATION OF RHEUMATISM?

To the Editor of THE MEDICAL NEWS,

SIR: In an article, "The Dietetic Treatment of Some Important Neuroses" (THE MEDICAL NEWS, January 2, 1892), Dr. John Ferguson, of Toronto states that uric acid is a prime or the sole factor in producing many neuroses—epilepsy, chorea, hysteria, migraine, etc.—by its action as an irritant poison, circulating through the tissues of the body, when produced in excessive quantity—to cause an "overflow," so to speak, into the circulation.

In my experience with rheumatic affections, I have so frequently noticed this excessive formation of uric acid, as shown by an examination of the urine, that I regard it as symptomatic of a tendency to rheumatic troubles, even before the patient has the attack. Uric acid is produced in the system by a stimulating, nitrogenous diet and the use of alcoholic beverages. In the treatment of rheumatic affections we first prohibit entirely, or allow very sparingly, according to the nature of the case and the condition of our patient, an animal diet and alcoholic beverages, especially wines and beers. Next we give the saline mixtures of potassa and soda and the salicylates. Why? Because clinical experience shows such the best course to pursue.

Does not this treatment lessen the quantity of uric acid, which, by its irritating influence upon the lower-grade tissues of the body, gives rise to the rheumatic attack, consequently checking or "curing" the rheumatism? A case of sciatica, due to rheumatism, remains quiescent so long as the excretion of uric acid is normal in quantity, but as soon as the urine shows an excess, exacerbations manifest themselves, which disappear as by magic when the quantity is lessened to normal by a few doses of salicylate of soda or carbonate of lithium—washing out, as it were, the excess of uric acid from the system.

If such be the case, as clinical experience tends to show that uric acid in excess is a sole or prime factor in the causation of rheumatic affections, have we not the "key" of the trouble, whereby we may prevent a rheumatic attack in the education of our rheumatic patients to abstain from too free indulgence in an animal or nitrogenous diet and the imbibing of alcoholic beverages? Also, in the examination of their urine, as to quantity, appearance, hyperacidity, etc.; in the use of the mineral waters—Vichy, Seltzer, Carlsbad, etc.—as occasion may demand.

If such a course were universally followed, how much of the suffering of humanity might be greatly alleviated or wholly prevented! and a step made in advance in the prevention of disease.

W. E. SHOTWELL, M.D.
DENVER, COLORADO.

THE ALABAMA LAW AS TO MEDICAL EXAMINATIONS.

To the Editor of THE MEDICAL NEWS,

SIR: I notice the following in your issue of January 16th: "The State of Alabama has passed a law requiring all physicians who are not graduates of reputable medical schools to obtain certificates of qualification from a board of medical examiners." Our law has been in operation for ten years and it requires *everyone* wishing to practise in the State to first obtain a license from "the County Board of Medical Examiners." Before being allowed an *examination* he must first show a diploma from a reputable medical college. We have also a

State Board of Examiners, to which all papers are sent for approval. Any applicant failing to pass a County Board may appear for re-examination to the State Board. No physicians in the State practise without a diploma, except a few who had been in practice for five years before the law was passed.

Very sincerely,
GEORGE S. BROWN, M.D.,
Secretary of Board of Medical Examiners.

BIRMINGHAM, ALA.

OBITUARY.

SIR MORELL MACKENZIE.

IN the fifty-fifth year of his age, this famous physician, whose phenomenal career has attracted world-wide attention, has succumbed to bronchitis, a sequel, in all probability, to an attack of the prevalent and pandemic influenza. Graduating in medicine about the time that Czeomak, of Pesth, was travelling through Europe to demonstrate the physiological and diagnostic uses of the laryngoscope, young Mackenzie recognized its usefulness in advance of all but a very few of his medical colleagues, and he cultivated its professional use with such assiduous energy as soon made him its leading exponent. Hence, when a few years ago the Crown Prince of Prussia was known to have a malignant disease of the larynx, the services of Dr. Mackenzie were solicited, and for these he was knighted at the hands of his Queen. This increased his practice and his income.

Dr. Mackenzie's charmingly written journal articles and monographs, usually rich in historic research, attracted many readers, and soon drew to his special hospital crowds of students from different countries, among them hundreds of Americans, Canadians, citizens of the United States, and residents of Central and of South America. In many a town in these United States, and in all likelihood in many other countries, the fact that an aspiring specialist announced himself as a former assistant or as a pupil of Mackenzie, was sufficient to win the confidence of many of his professional brethren. Many of the leading laryngologists of London and Great Britain to-day were at one time his favorite pupils.

Dr. Mackenzie's phenomenal success in securing patients at home and from abroad produced a good deal of jealousy on the part of a number of the more conservative practitioners of his day, and his methods a considerable amount of distrust, from the effects of which his professional repute suffered more or less during his entire career; but he continued his work in his own manner independently of disregards or of covert and open sneers.

The true inwardness of Mackenzie's course in the case of the late Emperor Frederick, may possibly be disclosed in some posthumous publication; but the fact remains that that very sensible potentate stuck to Mackenzie to the very last moment, notwithstanding the unhappy progress of his case and the consequent scornful actions and comments of the other medical attendants. Hence he must have endured and approved of Mackenzie's conduct, right or wrong.

A career of practice such as spread the name and the fame of Morell Mackenzie, even to the remoter portions of the globe, had not occurred in the previous history of medicine.

NEWS ITEMS.

The Fifth District Branch of the New York State Medical Association will hold its eighth annual meeting in Brooklyn on Tuesday, May 24, 1892. All Fellows desiring to read papers will please notify the Secretary, E. H. Squibb, M.D., P. O. Box 94, Brooklyn.

University of Pennsylvania.—The Alumni of all departments of the University of Pennsylvania will give a dinner on the evening of Saturday, February 27, 1892, at Musical Fund Hall, with the object of bringing together a large number of the graduates of the University in social intercourse in a dignified and agreeable manner. It is also designed by this reunion to inaugurate a series of triennial dinners, which will serve to mark various epochs in the life of the University.

DR. ZEOVIA OWEN-MCDADE died recently, of acute pneumonia, in Kenyon, Minn., after an illness of three days. Dr. Owen received her degree at Michigan University in 1888. After nearly a year of study in Europe she returned to this country and married a classmate, Dr. C. W. McDade, engaging in practice in Nebraska, but removing to Minnesota last summer.

BOUCHUT, the distinguished French clinician, is dead.

SYSTEMATIC EXAMINATION FOR RECTAL DISEASE.[1]

BY R. H. WORTHINGTON, M.D.,
OF DENVER,
MEMBER OF THE BRITISH MEDICAL ASSOCIATION; RECTAL SURGEON TO ST. LUKE'S HOSPITAL, DENVER.

THERE is no way by which the different diseases of the rectum can be diagnosticated except by careful and thorough examination, and this in the large majority of cases can be made without the use of any instruments, and almost without pain to the patient.

When patients consult me I always encourage them to tell their own story in their own way, and usually they will give some salient points on which I can base my questions, though these points are frequently mixed up with irrelevant information.

The statement of a patient as to rectal disease may be very useful as a guide to the direction in which one should inquire further and search for lesions, but for diagnostic purposes it cannot be depended upon. In four cases out of five, the patient says he has piles. Very possiby he has. He may or may not, and he may have much more. If the surgeon simply takes the patient's word for it, and prescribes compound gall ointment, as is very frequently done, without making any examination, he has only himself to thank if his patient is not benefited, and goes to a quack for treatment. The fact of rectal disease being so largely in the hands of quacks is often because physicians habitually treat cases without a full examination, and therefore without a diagnosis, followed by a consequent failure to cure. The public has somehow got the idea that the regular profession can do little for rectal diseases, and so they naturally go to men who advertise their ability to cure. Most of the cases of carcinoma of the rectum that I have seen had been for several months treated for piles, without a digital examination having been made. Under such circumstances, failure to examine seems almost criminal.

After getting the patient's own account, I begin to question. How long has he suffered? The answer may throw much light on the case. If only *quite* recently, a thrombotic pile, abscess, or acutely inflamed internal piles that have hitherto escaped notice, may be looked for, or a recent fissure, or a polypus that has just come within the grasp of the sphincter, and that previously gave no trouble. Old internal piles may last indefinitely, as may fistulæ, though they usually tend to get worse before the patient seeks relief. Ulceration and stricture are usually of long standing, while carcinoma is, as a rule, discovered within a few months of its appearance, though its nature may not be understood until far too late for its removal with any hope of cure. Most patients put off seeking advice for rectal troubles till their condition is intolerable.

I then ask: "Is there pain?" Let the patient describe it. "Is it connected with the act of defecation?" "Is it acute, excruciating, or a dull, heavy ache?" "Is it constant or occasional?" "Where is it situated?"

The most acute pain is found in association with fissures and with ulceration situated within the grasp of the sphincter, and is aggravated or caused by defecation. A fissure may confidently be looked for when there is very acute pain always coming on with or shortly after a movement of the bowels, and lasting for half an hour or for several hours.

The pain of ulceration varies greatly according to the position of the ulcers, those situated high up being much less painful than those constantly irritated by the action of the sphincters, low down, near the anus—probably the most sensitive part of the body.

Some simple ulcers occasion but little pain, and syphilitic ulcers are, as a rule, much less painful than the tuberculous ulcers, which are probably the most painful of any, and the most difficult to cure.

Fistula may occasion much pain if the internal orifice is large and the external one small, or if the skin is much undermined; but if the external opening is large enough to allow of free drainage, and is kept open, the pain is slight.

Uncomplicated internal piles rarely give rise to much pain, unless they prolapse, when there may be considerable. Inflamed external piles and the thrombotic external piles caused by the rupture of a vein at the anal margin, cause a good deal of pain, with dull, heavy aching and throbbing, much like the pain of abscess, but less severe.

The pain of coccyodynia is spasmodic, usually attacking the patient when attempting to rise from a sitting posture. Some of these cases are purely neuralgic, while the worst ones are due to caries of

[1] Read before the Denver Medical Association and Arapahoe County Medical Society, October 13, 1891.

the coccyx, or to disease of the sacro-coccygeal articulation.

Very frequently I have examined patients who complained of pain in the rectum or about it, and who were firmly convinced that they had some rectal disease, but in whom the rectum and anus were entirely free from any discoverable lesion. In such cases the cause may usually be found in some neighboring organ, the pain being reflex. Urethral stricture, stone or tumors of the bladder, and enlarged prostate in the male, or an enlarged and misplaced uterus, with the fundus or cervix pressing abnormally on the rectum, or a prolapsed ovary, in the female, may cause these pains, as may also any pelvic tumor.

Then, again, in severe ulceration and in carcinoma of the rectum, pain is frequently felt down the legs, especially the left, and this may be the first symptom that causes the patient to seek advice. Old-standing prolapsing piles are sometimes accompanied by constant backache. A patient on whom I operated lately told me a few days after the operation that he was then free from backache for the first time in five years.

To return to our questions. Is there any bleeding? If so, is it constant or occasional, slight or profuse—or merely a streak of blood in the feces?

Internal piles are by far the commonest cause of rectal bleeeding, especially if profuse and occurring with every, or nearly every, movement of the bowels. Hemorrhage occurs also in association with carcinoma when it has reached the stage of ulceration, and with polypi, which are the usual cause of rectal hemorrhage in children. It is astonishing what an amount of blood may be lost daily from a very small pile, or a little warty polypoid growth not larger than a pea. The bleeding from non-malignant ulceration and from fissure is much less profuse—in fissure frequently merely a streak of blood in the feces. In ulceration and in some polypoid growths, there is often a discharge of dark blood, mixed with mucus, early in the morning, and in bad cases recurring at intervals during the day, while fecal discharges may be quite free from blood.

Dysentery must, of course, be remembered, and also vicarious menstruation, which occasionally, though rarely, occurs from the rectum.

Does anything protrude from the rectum during defecation? Does it return itself, or can it be returned, and if so, will it stay up?

External piles are usually described as coming down from inside the anus, but they cannot be put back and kept in. Internal piles, carcinomatous and other tumors, polypi and small polypoid growths, may all prolapse. In procidentia there may be merely a small prolapse of the mucous membrane or an immense mass protruding, in some cases as large as a child's head, and involving all the coats of the intestine. In these severe cases of procidentia, a hernia should always be looked for (it lies on the anterior aspect of the bowel), and if present is a serious complication.

The causes of procidentia must be carefully searched for. It is often due to polypus, sometimes to piles, and if so may be entirely relieved when the cause is removed. In a case I saw recently there was an epithelioma of the posterior rectal wall, which, however, was probably secondary to the procidentia and caused by the irritation of the exposed membrane.

Is there any discharge from the rectum? is another question I usually ask.

A discharge of mucus, with or without pus and blood, is pretty constant in association with ulceration, and often accompanies old internal piles. It may result from polypus and small polypoid growths, and some may be found in connection with a catarrhal condition of the colon. There is much discharge in the later stages of carcinoma, and there is some with fistula.

An exudation from and around the anus usually accompanies pruritus, and is often due to eczema. It is especially marked at night when the patient gets warm in bed, and then the itching usually becomes intense. Itching, by the way, does not always mean pruritus, but is sometimes the first premonitory symptom of the formation of an abscess, often a deep one.

I never fail to inquire about the state of the bowels. Many rectal ailments are due to constipation, and are relieved when it is overcome. It must be remembered that diarrhea may accompany an impaction of feces in the rectum or colon, and an enormous load may be found there in spite of the patient's belief that such a thing is impossible because he has had a diarrhea for a week or more.

It is often well to ask if a satisfactory movement is obtained; if the rectum seems to be emptied, or if there is something left that straining does not bring away. This symptom may be found in connection with a polypus, with an internal procidentia or partial intussusception of the rectum, or even with a pile within the grasp of the sphincter. Stricture, of course, causes a difficulty in defecation, and very similar symptoms may be due to an enlarged prostate or to a retroverted and tender uterus.

After questioning the patient I invariably make a physical examination, preferring to have the patient lie on the left side, in the Sims position, and in a good light.

Inspection of the anus may give much information. An abundance of fine silky hair usually denotes a tuberculous patient, with whom any extensive

operation should, if possible, be avoided, and with whom chloroform is to be preferred to ether, for fear of exciting or aggravating a cough, the succussion of which in a rectal wound gives great pain and prevents healing.[1]

Note any discoloration, the red blush and swelling of an abscess, or the loss of pigment that occurs in pruritus, leaving the skin at the margin of the anus of a dull-white color. With pruritus there is frequently chronic eczema, and a thickening of the skin, sometimes close to the anus, sometimes an inch or more away from it. The characteristic itching usually becomes worse at night when the patient is warmed in bed. The laity know it as "itching piles." Piles are frequently found with pruritus, and the latter may disappear on the removal of the former. Pruritus may also be dependent upon a fistula, or any other local disease, and such causes (caries is a common one) must be carefully sought for; very frequently, however, pruritus is found in connection with a congested liver and a gouty or lithemic condition, and is aggravated by any excesses in living and by the use of coffee and by smoking.

A glance at the anus tells if there is any kind of external piles and tabs, these being usually the remains of old piles. When these tabs, or cutaneous external piles, as they are often called, are found swollen, shiny, and bathed in a discharge from the anus, they are significant of serious ulceration higher up, usually syphilitic or carcinomatous. Syphilitic sores and vegetations, and warty and other growths, and the scars of previous operations, should be observed.

By feeling around the anus with the pulp of the forefinger the indurated tracks of fistulæ can be traced beneath the skin, and by a little pressure along the track a drop of pus can frequently be made to exude from the orifice, which otherwise may be hardly perceptible. The orifice of an old fistula is frequently soft and pouting, and the discharge thin and watery. Such a fistula can be left for a while without operation with more safety than one discharging thicker pus, as the latter is in an active state and much more liable to burrow further. Careful search should be made in folds of skin and around the bases of tabs for small fistulous openings and fissures that may easily escape detection.

By telling the patient to strain, and at the same time placing the fingers on either side of the anus, and gently but firmly drawing the buttocks apart, nearly half an inch of the anus can be exposed, and fissures, polypoid growths, the openings of fistulæ, and perhaps internal piles, can be seen.

[1] A dry, harsh condition of the skin about the anus, with a number of small cracks or fissures radiating from it, is found in victims of the opium-habit.

In married women, a small portion of the anterior rectal wall can be everted by introducing the forefinger into the vagina and pressing it out of the anus. This is very useful in examining fissures situated anteriorly, or the perineal pile so frequent in women, but except in such cases it is of little use, as only a very small portion of the rectum can be seen in this way.

The forefinger, well anointed with vaseline or some other lubricant, should next be inserted into the anus. The pulp of the finger should be placed *on* the anus, and the patient told to bear down. As he does so, the sphincter is relaxed and the finger slips in easily, and much pain is avoided. At first, the finger should only go in a very short distance, just passing the external sphincter, and the surface of it should be swept over, as well as the space between the external and internal sphincters. This is the usual site for the openings of fistulæ, which can be detected by the educated finger, feeling sometimes like a dimple, and sometimes pouting and feeling like a gumboil.

If the indurated track of a fistula has been detected externally running posteriorly to a line directly across the center of the anus, the internal opening will be found in about nine cases out of ten in the median line directly posteriorly, no matter where the external orifice may be. It is of the utmost importance, before operating, to find the internal opening, because the sphincter must only be divided at one point, and that point is where the track from the internal opening passes under or through the sphincter.

Fissures rarely extend above the line between the two sphincters. As the finger passes over them, they are easily detected, and their extent ascertained. This space between the two sphincters is also a frequent seat for ulcers, the surface of which has a rough feel. Polypoid growths may be found here, as well as below and above.

The finger may then be passed over and above the internal sphincter, and swept around. Note any enlargement of the prostate, or if the uterus presses abnormally on the rectum, and is tender. Feel for ulcers and the tracks of fistulæ extending high up, the soft, fluctuating bulging of abscess, or any induration and narrowing of the canal by stricture, or by carcinomatous or other tumors. By bending the finger directly posteriorly, the anterior surface of the coccyx can be explored, and any tenderness of it or about the sacro-coccygeal joint detected.

Finally, the finger should be inserted to its full length to ascertain if there is any stricture or growth high up. More length can be gained here by keeping the other finger extended and pressed between the buttocks posteriorly, and should the symptoms call for such a measure, by having the

patient stand on his feet and strain down. Hardened feces are frequently felt at this stage, and may easily be mistaken for a carcinomatous growth. Find if the mass can be indented, and scratch it with the finger-nail. On withdrawing the finger, see if it is smeared with fecal matter, or with mucus, pus, or blood.

If the rectum is found loaded with feces an enema should be given and the patient examined immediately afterward. In some cases the enema is most useful, even if the bowel is empty. By this means a fibroid polypus with a long pedicle may be brought within reach and the finger hooked over the pedicle, when otherwise it may escape detection by returning higher up the bowel. Prolapsing internal piles will also be brought down, and can be inspected.

Internal piles are most difficult to detect by touch alone. The finger must be very well educated to recognize them. They usually lie on or below the internal sphincter, and can be detected by slightly crooking the finger and sweeping it around. In this way the sulci between the piles can be felt and the tumors themselves recognized.

Now, all this can be done by the intelligent use of the finger in the way I have described, and there are very few pathologic conditions of the rectum that, with a minimum of pain to the patient, cannot so be diagnosticated. The feeling is all done with the pulp of the last phalanx of the finger, and the mistake that is usually made by the inexperienced examiner is that of inserting the finger at once past the internal sphincter into the rectal pouch, and nothing abnormal being found there, withdrawing it without exploring either above or below. Lesions high up are not reached, and the sensitive part of the finger does not come in contact with those below, or it passes by them too hastily to notice their presence. In the large majority of cases the lesion lies within about an inch of the anus.

In many cases of fissure, and even of ulcer at the sphincter, the finger cannot be introduced without causing great pain. In some of these cases the application to the sore of a solution of cocaine, from 5 per cent. to 20 per cent., on a pledget of cotton, may cause sufficient local anesthesia to permit an examination; but in most cases it will be necessary to administer ether and dilate the sphincters, and so explore thoroughly, being prepared at the same time to do any operation that may be found necessary.

The speculum has but a limited use for purely diagnostic purposes. It is frequently useful in verifying the diagnosis made by the finger, and in searching for the opening of a small blind internal fistula, or for small lacunæ, or "pockets," near the anus, that occasionally give trouble; but its use will be more and more dispensed with as the surgeon becomes expert with his finger. The speculum often gives great pain, and if opened sufficiently wide for a thorough exploration its employment will frequently require the use of an anesthetic.

The diagnosis of stricture beyond the reach of the finger and in the sigmoid flexure is replete with extreme difficulty, the more so since the inability to pass a full-sized bougie is no evidence that there is a stricture except after repeated trials in skilled hands. I have seen Mr. Herbert Allingham pass his ball-staff into the sigmoid, but I have never succeeded in doing it myself, and Dr. Kelsey speaks of his inability to use the instrument satisfactorily. A bougie will usually be arrested at the promontory of the sacrum, and will also be caught in the folds of the mucous membrane. This may be partially overcome by using the soft rubber bougie, through which water can be injected and the folds drawn out of the way by dilating the intestine, but exploration of this region is always difficult and unsatisfactory.

Occasionally the introduction of the whole hand into the rectum, after the method of Simon, of Heidelberg, may be used to advantage, but it is a procedure full of risk to the patient, several deaths having been recorded from rupture of the intestine. If the symptoms point to stricture high up, and a satisfactory diagnosis cannot be made with bougies, I prefer to make an abdominal exploration, making the incision as in inguinal colotomy. There is little danger in this, and, if necessary, the colotomy can be done at the same time.

A REPORT OF EIGHT ADDITIONAL CASES OF PERINEAL SECTION WITHOUT A GUIDE.[1]

By J. EDWIN MICHAEL, M.A., M.D.,
of Baltimore, Md.

In the spring of 1887 I had the pleasure to read before the Medical and Chirurgical Faculty of Maryland a report of nine cases of perineal section without a guide. The paper was published in *The Annals of Surgery*, in July of the same year. Of these cases the operation was performed in one for old perineal contusion, in five for old gonorrheal stricture, in two for old pelvic fracture and resulting traumatic stricture, and in one for recent pelvic fracture. One of these cases died from carcinoma about a year after operation, and one from tuberculosis six months after operation. The rest, so far as I am informed, with the exception of Case VIII, who has since died of tuberculosis, are still alive and well. Since the publication of my paper I

[1] Read before the Southern Surgical and Gynecological Association, at Richmond, Va., November 10, 1891.

have been doing more work in the same line, and I propose in the present paper to report eight additional cases that have come under my care.

The operation is one of great value, both in gonorrheal and traumatic cases, and I think one is justified in bringing forward any experience in it that may be of use to the profession. My results, as will be seen, are very satisfactory—a fact that I attribute rather to the fortunate circumstance that my patients were largely free from grave constitutional disease than to any method or application that I have to suggest. I have simply followed what I consider the precepts of good surgery as applied to this region of the body, viz.: free incision, free drainage, and so much of antiseptic surgery as the circumstances will allow.

Case I.—W. T., fifty-one years of age, a bricklayer. He had gonorrhea at twenty, and has had several attacks since. At twenty seven a stricture developed, and gave him much trouble. Retention of urine occurred several times, and had to be relieved by the catheter. He has suffered a good deal of late from difficulty in urination, much straining being necessary, and the stream being very small. On May 9th, while making strenuous efforts to void his urine, there was felt sudden and severe pain in the perineum, followed by some relief from the desire to urinate and the early development of a painful swelling. When I saw patient, on May 13th, I was unable to pass an instrument into his bladder. The perineum was much swollen, and the scrotum and lower abdomen showed every evidence of extensive extravasation of urine. On the right side the swelling extended to the umbilicus, and well over toward the loin. The circumstances by which the patient was surrounded made operation at home practically impossible, and I had him removed to the Maryland University Hospital. On the following day I made large incisions into the connective tissue of the perineum, scrotum, and abdominal wall, freely laying open all the structures involved in the infiltration. I then sought the urethra in the perineum, and after only moderate trouble found it, and laid it freely open. The strictured bulbo-membranous region was then attacked from behind and freely incised, the operation terminating by passing a sound (No. 18 English) into the bladder through the urethra. Recovery was complicated by a considerable secondary hemorrhage from the abdominal incision several days after the operation, but in other respects the patient did well, the temperature not reaching above 101°. Sounds were passed on every third day, the wounds made on account of the urinary infiltration rapidly healed, and the patient left the hospital in about six weeks, in good condition, and able to pass a sound (No. 20 English). I have seen the patient within the last few months, and he tells me that his condition is satisfactory, and that he can pass a good stream of urine.

Case II.—C. H., thirty-eight years of age, a waiter. He entered University Hospital on April 1, 1888, suffering with stricture of the urethra and perineal fistulæ. Ten years ago he had repeated attacks of gonorrhea, and suffered several times from retention. About five years ago, after an attack of retention, two small fistulæ formed in the perineum. Urine escaped from these openings in small quantity for about six weeks, when they closed and remained closed for about six months. After this they opened, and discharged from time to time. The patient suffered often from retention, which was with difficulty relieved by catheterization, but he was able to continue at his work. On March 14th he fell into the hands of an electrical expert, by whom electrolysis was practised. Whether *post* or *propter hoc*, a perineal abscess followed. This was opened in the dispensary before his admission to the hospital. Upon admission the patient was in a deplorable condition. He was able to pass very little water, and that little in driblets, through his urethra and fistulæ with much pain and straining. Complete retention soon followed. Repeated attempts were made to relieve by catheterization, but no instrument could be passed. Anodynes and a hot sitz-bath brought some relief. On April 12th, all attempts to pass an instrument having repeatedly failed, the patient was etherized, and the perineal section without guide undertaken. The way to the bladder was again sought, both by way of the penis and the fistulæ, but in vain. The perineum was a mass of cicatrices, in which the urethra was vainly searched for, until, finally passing deeply into the perineum, the membranous portion was laid open and an instrument passed into the bladder. The strictured portion was then attacked from behind. When opened sufficiently for the purpose, the Otis urethrotome was passed, and the canal freely incised. After the operation a No. 18 English catheter passed easily through the urethra into the bladder. The hemorrhage in this case was tolerably free, but was kept measurably under control by irrigation with a hot solution of sublimate, 1 to 1000. After completion of the operation, the hemorrhage continuing to be troublesome, the wound was lightly packed with iodoform gauze, and the patient's legs tied together. In the evening of the day of operation the patient was comfortable, and had a temperature of 98° and a pulse of 80. At 5 o'clock on the following morning there was a lively chill, and the temperature ran up to 105°, with a pulse of 120. The wound was unpacked and irrigated with sublimate solution, the water drawn by catheter, the bladder washed out with plain warm water, and the wound lightly packed and dressed as before with iodoform gauze. On the evening of the same day the temperature was 99°, and the pulse 108. No further complication occurred. A sound was passed on the third day, and regularly thereafter, and at the end of a week the patient was walking about the ward. At the end of the second week, all of the urine passed naturally, and both fistulæ and operation-wound were nearly healed. In the meantime the general health greatly improved, and when the patient left the hospital, about four weeks after operation, he was passing a good, full stream of urine, three or four times a day. I have no later information in regard to this patient's condition. The

case is especially interesting to me, not so much on account of the brilliant ultimate result of the operation as on account of the associated facts that the free hemorrhage made it necessary to pack the wound, and that there was such a decided urethral chill on the morning of the second day. The chill itself was a beautiful example of its class. On the day of operation the temperature was normal. On the morning of the next day it suddenly shot up to 105°. Within twelve hours it was practically normal again, and continued so until the patient was discharged. This fall of temperature occurred without antipyretic treatment, save irrigation of the wound and bladder, and re-dressing the perineum.

Case III.—J. H., twelve years of age. The boy was coasting, and fell from his sled with his head down hill and his feet up. The sled of a companion following close behind him struck him in the perineum, causing considerable bruising of the part. He paid comparatively little attention to the injury, and did not even mention it when he returned home. After being at home some little time he felt the desire to urinate, and went to the closet. Upon making the attempt he was surprised to see a drop or two of blood issue from the penis, and to find that he could not pass water. The family physician, Dr. W. F. A. Kemp, was called in, and attempted to relieve the boy by passing a soft catheter. The attempt failed, and the doctor asked me to see the patient. On the following morning, January 29, 1888, we met at the patient's house. The perineum was by that time pretty black, and the penis and scrotum considerably swollen. Attempts to pass instruments having failed, ether was administered, and the perineum laid open. The tissues were much contused, and a considerable clot was turned out. With some difficulty the urethra was found. A No. 8 English steel sound was passed through the wound, and we were astounded to see that it went in very smoothly, and continued to go without meeting any resistance until the shaft of the instrument was flush with the perineal wound, and the point easily felt under the abdominal wall, immediately below the umbilicus. The specter of ruptured bladder momentarily appeared to us, but when we reflected that there was no sign of shock or other grave symptom, we were comforted. A soft catheter brought away twenty-four ounces of normal urine, and relieved our apprehensions as well as the patient's bladder. There was moderate oozing from the wound, but not enough to give trouble. The wound was well cleansed and lightly dressed with iodoform gauze, and the patient put to bed. The subsequent course of the case was uneventful. Sounds were passed at intervals of a few days, and the patient made a good recovery. The interesting point in this case to us was the extent to which the sound passed up into the bladder when the urethra was first opened. Finding, however, that the sound passed up almost as high after the bladder was emptied, we concluded that the fusiform shape of the infantile bladder was in this patient retained to an unusual degree.

Case IV.—G P., forty years of age, a physician, had led a very irregular life from early youth, and among other accidents had had gonorrhea many times. He had been long aware of the fact that he had stricture of the urethra, and had treated himself occasionally during the quieter periods of his life. He was an alcoholic and an opium-eater, and his urine contained a moderate quantity of albumin and casts. Attempts to pass instruments became more and more difficult, until finally, in February, 1889, their passage became impossible. The urine still trickled away by drops, and the patient had to be aspirated on several occasions. Neither he nor I were able to pass an instrument through the urethra, and as his condition was growing more serious from day to day, I recommended external perineal urethrotomy. The patient hesitated somewhat, but finally consented. The operation was an unusually easy one. The stricture was in the bulbo-membranous portion. I did not attempt to go through it, but operated back of the affected region, and sought the membranous urethra. On this occasion I opened the urethra in less than eight minutes after making the first incision. After emptying and washing out the bladder, the stricture was attacked from behind and easily incised. A No. 18 English sound was passed through the urethra as the final step in the operation. The wound bled little, and was dressed as usual by lightly packing it with iodoform gauze. The patient was nervous and somewhat feverish for several days, and gave cause for uneasiness on account of his general condition, but ultimately made a satisfactory recovery. The perineal wound healed kindly, and when the man left the hospital at the end of three weeks a No. 18 English sound passed readily, and the stream of urine was full and free.

Case V.—F. Q., forty-three years of age, entered the hospital in December, 1888, with the following history: He had gonorrhea in 1868, and another attack in 1883. In 1884 he began having trouble in passing water. He then entered the hospital, and was treated by gradual dilatation, beginning with a filiform bougie, and working up to a No. 18 of the English scale. He left the hospital in good condition, and with instructions to return every few days to have an instrument passed. After a few visits he neglected to do this, and shipped as a sailor on a vessel leaving Baltimore. He had no trouble, however, until July, 1888, when he returned to the hospital in a worse condition than before. He was passing water by drops, and it was found impossible to introduce an instrument into his bladder. After several aspirations, and continued failure to pass instruments, it was determined to open the perineum. On January 3, 1889, the patient was etherized and the operation performed. The stricture was in the bulbo membranous portion, and the deep perineum was in good condition. In this case I first adopted a method from which I have since had great satisfaction, viz., that of using scissors after making the first incision. Making a free incision from the scrotal reflection to the verge of the anus with a bistoury, I passed a thread through the lips of the wound as usual, for the purpose of keeping the parts exposed. Then taking sharp-pointed scissors, and being enabled in that way to keep rigidly in the

median line, I went straight ahead, and was very agreeably surprised in being able to open the urethra in just eight minutes from the moment of making the first incision. I opened the canal behind the stricture, and easily passed a large instrument into the bladder. That viscus having been emptied and well washed out, I attacked the stricture from behind and opened it freely. As the final step a large sound was passed through the whole urethra into the bladder. There was no hemorrhage of any consequence. The wound was dressed as usual. The temperature chart shows 100° on the third day, and a practically normal line afterward. Sound (No. 18 English) was passed every third day, and the patient left the hospital February 2d, well.

Case VI.—C. E. K., twenty-four years of age, entered the hospital January 22, 1889, with the following history: While cutting timber in June of the previous year the patient was caught between two trees and very severely crushed. He was carried home, and seen by Dr. J. Lee McComas, of Oakland. The doctor found extensive fracture of the pelvis, and a ragged wound at the right side of the perineum. The patient was kept quiet in bed, and no special treatment used except with a view to overcome shock. In a few days a large swelling developed in the perineum and toward the inner surface of the right thigh. This was opened, and discharged a large quantity of pus, together with a splinter of wood as big as the little finger. Later, feces, urine, and pus passed freely from this opening. When the patient entered the hospital, feces had ceased to pass by the fistula, but pus and urine continued. Some urine also passed by the penis, but this, as well as that which passed by the fistula, was mixed with pus. The right thigh was fixed in the flexed position, somewhat adducted, and the tuberosities of the ischia were only two inches apart. No instrument could be passed into the bladder, but on the right the probe could be passed far up the fistulous tract. On March 1st the patient was etherized, and external perineal urethrotomy performed. The operation was very difficult, and took a long time. The distortion of the pelvic bones, as well as the cicatricial condition of the soft parts, robbed me of all anatomical aid, and the only guide I had was the prostate gland, which I could feel through the rectum. Finally, however, the bladder was reached and washed out, the urethra opened, and a large soft catheter passed and tied in. This procedure, which I abominate, and never use if I can help it, was necessary in this case, as will be readily seen from the preceding description of the parts as I found them. By using a wooden plug, the catheter was controlled and the urine evacuated at will. The patient did well for the time, and at the end of two weeks went home under the care of Dr. McComas. Later, however, he removed the catheter from the bladder, and was not able to replace it. He continued doing reasonably well for a time, but grew worse again, and returned to the hospital in January, 1890, in as bad a condition as before, with the addition of much cicatricial tissue in his perineum. I tried again to make the section, but failed, and subsequently established the continuity of the urethra by first making an epicystotomy, and then passing a sound from above the pubes through the prostatic urethra, and cutting down on it in the perineum. A long tube was then passed through the epicystotomy-wound, and out through the urethra, with drainage-holes in the part that occupied the bladder. This operation gave the patient considerable relief. There was, however, much bone-exfoliation from the interior of the pelvis, which kept up the fistulous discharge; and although when he passed from my care the continuity of his urethra was established, he was still suffering much from the other effects of his serious injury, and will in all probability never be restored to full health. I was never able to determine the exact degree of injury inflicted in this case, nor to understand perfectly the mechanism of it. The main traumatism seems to have been an almost fatal squeeze between the two trees, which fractured the right half of the pelvis in some way. In addition to this there was a wound made by the perforation of the perineum by the splinter of wood referred to. Which of these wounds produced the damage to the urethra and rectum, thus causing feces, urine, and pus to escape from the same opening, it is difficult to determine. Several pieces of bone of considerable size were removed from the fistulous tract during the second operation, but they were so changed that it was impossible to say to what spot they belonged. The spines and crests of the ilia seemed normal, but the approximation of the tuberosities showed that there must have been pelvic fracture with considerable displacement. Cases VII and IX of my former series illustrate the manner in which the fractured extremity of the ischio-pubic ramus is thrust into the perineum, crushing all of the soft parts in the way, but I am by no means sure that this is the mechanism of the traumatism now under discussion. This case is also particularly interesting to me, as it is the first in which I was unable to reach the urethra in the perineum after repeated trials. The method of finding the urethra by retrograde catheterization is one I have had in mind for a long time, but up to this time I have had no occasion to use it. It was first used by Brainard, of Chicago, in 1849, and has since been used by others, but it is not so much as mentioned in many books on venereal surgery. The ease, comfort, and safety with which this operation can be performed made a great impression on me, and I have made up my mind never again to undergo the trying ordeal of a long and tedious perineal section, especially on a patient with a full bladder. In cases in which the stricture is in the usual place, and there has been infiltration or the formation of fistulæ, the section without a guide is not difficult, and the supra-pubic opening is not necessary; but when one has to operate in a mass of cicatrices, and cut and feel from hour to hour, and perhaps at last find that he has been within a hair's breadth of the canal all the time, the supra-pubic incision will save much time and hard work, as well as much unnecessary wounding of the perineal tissues.

Case VII.—J. H., colored, thirty-five years old, a laborer. I was called to see this patient by Dr.

R. M. Hall, of Baltimore. Finding the circumstances such that I could not treat the patient satisfactorily at home, I recommended that he be taken to the University Hospital. He gave the following history: He had had the usual diseases of youth, but denied venereal disease of any kind. On March 1st, while carrying a hod of mortar, he slipped and fell across a plank. He does not think he was struck in the perineum, but afterward had trouble in passing urine, and his water was stained with blood. He continued to work until March 7th, when he had an attack of retention. An instrument was passed, but no urine flowed. Afterward he passed blood and then urine. He noticed a swelling in the perineum that gradually crept up the right groin and affected the scrotum. When first seen (March 15th), he presented the picture of a man with a rather large inguinal hernia. Soon after admission, on March 16th, complete retention having supervened and attempts to pass instruments having failed, the perineum was laid open, and a large amount of stinking pus evacuated. The urethra was easily found, because the burrowing pus had made a pretty clean dissection of it, and it stood out in the wound like a cord. The canal was opened, but the sound failed to pass into the bladder by reason of a tight stricture back of the point of incision. A fine director was, however, insinuated through the stricture and followed by a bistoury, and the constriction incised. A large sound was then passed through the whole length of the canal. The burrowing of the extravasated urine and pus had been so extensive that the wound now was a veritable yawning chasm, which extended from the deep perineum through the right half of the scrotum to the hypogastrium. The room in which the operation was performed was scarcely habitable by reason of the fetid odor of the pus and urine that had been evacuated. Yet the general condition of the patient was, on the whole, satisfactory. The cavities were loosely filled with iodoform gauze, and the perineum dressed with a large, loose pad of the same, backed by absorbent cotton. On the third day the temperature rose to 104°, and for several days thereafter was somewhat irregular. On March 22d a large abscess was discovered in the left buttock. This was incised and drained. After this, improvement was more manifest and the patient recovered gradually. A No. 18 English sound was occasionally passed. When discharged from the hospital, at the end of a month, the patient had almost recovered his full health.

Case VIII.—R. R , about twenty-five years old, a carpenter, on October 11, 1891, fell astride the round of a ladder and hurt himself. He did not, however, regard his injury as of much consequence. Finding that when he attempted to urinate only a little blood came, and that his perineum was beginning to swell, he called his physician, Dr. J.W. Laird, who attempted to pass a catheter. The attempt failing, I was called in consultation. I also failed to pass an instrument, as was to be expected, and immediately proceeded to make the section. The patient was a man of nerve, refused to be anesthetized, and exhibited admirable fortitude during the operation. The perineum was freely laid open from scrotal reflection to the verge of the anus. Some clotted blood and much bruised tissue was exposed. The dissection was carried down in the median line with scissors, and the urethra easily found and opened. The case progressed well, and the wound healed kindly. There was, however, some difficulty in passing urine. Some weeks after the operation I saw the patient, and made a hurried attempt to pass an instrument, but failed. There was no urgency in the symptoms at the time, and I asked him to come to me at another time. Since that visit I have not seen him, and so cannot give the ultimate result of the case. So far as the operation is concerned, however, it was easily done, and served its purpose perfectly, and probably saved the patient much suffering from urinary infiltration and suppuration of the perineum.

Remarks.—The report of these eight cases brings up the number of patients on whom I have made the operation of external perineal urethrotomy to seventeen, and the conditions that made that operation necessary include nearly all of those that ordinarily indicate it. None of the patients have died at a period earlier than six months after the time of the operation, and the deaths that have occurred were due to other causes. I have only to add to the remarks made at the conclusion of my last report, that increasing experience leads me to have more and more confidence in the good results of opening the perineum, and less fear of danger. It is true that I have had unusually good fortune in operating on cases that, as a rule, presented no grave kidney lesion; but while it must be admitted that such complication adds to the risk of the operation as such, if not more than it does to others of equal gravity, I am firmly convinced that opening the perineum in old stricture cases with bad kidneys is much freer from danger than internal urethrotomy, or even dilatation. A case in point may not be out of place.

About ten years ago I did an internal urethrotomy on a patient with an old tough stricture. In forty-eight hours he had a temperature of 107°, and was very ill. The same patient returned to me a few weeks ago; I could pass a No. 10 English sound with difficulty. The stricture was resilient and closed after the sound to such an extent that urination was difficult and unsatisfactory. The patient had been having chills, and was somewhat nauseated and weak. His urine, although ammoniacal and ropy, contained no evidence of grave kidney trouble. I proposed a combined internal and external urethrotomy, and refused to do either operation without the other. The patient consented. I opened the perineum freely, and cut the urethra with the Otis instrument to No. 40 French. The temperature did not rise above 100°. The patient did well in every particular, and in three weeks I sent him home, passing a No. 36 French instrument on himself.

FACIAL ERYSIPELAS COMPLICATING TYPHOID FEVER.[1]

BY D. N. EISENDRATH, A.B., M.D.,
RESIDENT PHYSICAN, COOK COUNTY HOSPITAL, CHICAGO.

OF all complications occurring during the course of or following as a result of typhoid fever, erysipelas in general, and especially the facial variety, is the rarest. Having had the opportunity to observe four cases during the past six months, I desire to add reports of them to the literature of the subject. The first two cases occurred within three days of each other—the patients occupying beds about thirty feet apart, upon opposite sides of the ward. Care had been taken to isolate the first case in a private room with a special nurse, but the same physicians visited both patients. The first case is as follows:

CASE I.—W. G. La C., a printer by occupation, twenty-six years of age, was admitted May 7, 1891, with a history of having felt dizzy, dull, and tired for three or four weeks, with gradual loss of appetite, and frontal cephalalgia, so that he was unable to look up. The bowels had been costive until relieved by laxatives ten days before admission, when they moved from four to eight times, the discharges being thin and light-yellow. Clots of blood had been daily removed from the nose, but there had been no epistaxis. The man had been unable to work and was obliged to go to bed fourteen days before coming to the hospital.

Upon admission, May 7, 1891, the patient complained of a dull and tired feeling. There was moderate tympanites, with extreme tenderness over the right iliac region. The bowels were moved twice in twenty-four hours, the feces being thin, watery, and fetid. The temperature was quite characteristic, and on May 15th there was a typical roseolous eruption. On May 18th there were severe epistaxis and marked muscular twitchings; the man was constantly picking at his nose.

On May 19, 1891, the twenty-seventh day after taking to bed at home, a well-defined erysipelatous swelling appeared on the right side of the nose and face. The pulse was rapid (120) and weak and the patient was placed in a private room with a special nurse. He was put on cardiac stimulants, whiskey, ammon. carb. and tr. digitalis every four hours, alternating with tr. ferri chloridi, ♏xv, with applications of wet boric acid dressings.

On May 21st the swelling had extended to the left side of the face and nose. There was a busy, muttering delirium, the pulse was weak and rapid (130), and there was marked tympanites. The man died May 22d. A post-mortem examination was made, but failed to reveal any but the usual typhoid lesions of the third week.

CASE II.—The second case, that of C. C., a laborer, admitted May 6th, occurred in the same ward three days after the discovery of the first case. The patient was twenty-eight years old and in robust health up to the beginning of his illness. This began ten days before admission, with all of the early symptoms of typhoid fever, which in the hospital became moderately severe, the afternoon temperature daily reaching 105°, but yielding to the full bath and antipyretics. On May 13th the urine contained albumin, and hyaline and granular casts. On May 14th the man had three severe intestinal hemorrhages, and upon the next day another of smaller amount, and he vomited an ascaris lumbricoides or round-worm. His temperature again rose to 104.8°, but gradually fell to 100° on May 21st, and the general symptoms seemed to be those ot beginning convalescence; but upon May 22d, the twenty-seventh day of his illness, a typical erysipelatous swelling, extending over both sides of the face, nose, and forehead, was noticed. The temperature again rose to 103° and the patient was removed to the isolation-ward under the care of a special nurse. Typhoid orders were stopped and wet boric acid dressings were ordered to the face and head, and tr. ferri chlor. ♏xx, whiskey ℥j, strych. sulph. $\frac{1}{32}$ gr., every four hours. Upon May 24th the man was restless and delirious in a busy and constant-muttering way. The erysipelas had spread to the eyelids, neck, and ears. The pulse was weak and rapid (140-160), and despite careful stimulation the patient died on June 3d, eleven days after the appearance of the erysipelas.

In both of the cases reported the complication markedly increased the gravity of the illness. Both had certainly passed the danger-point, the second after four hemorrhages, when the facial erysipelas began. There were no other cases in the regular wards of the hospital until October, 1891, after an interval of five months, during which time the special ward designed for erysipelas patients had been vacant.

The third and fourth cases occurred in different wards, but under the care of the same physicians—the third in the male, the fourth in the female medical ward—there being an interval of eight days.

CASE III.—R. R., German, female, twenty-seven years of age, entered September 25, 1891, having been ill for four days, with early symptoms of typhoid fever. Upon admission she presented a typical picture of the first week, viz., tremulous, whitish furred tongue, tenderness in the right iliac region, enlarged spleen, dulness and languor, and a stupid expression. The temperature was 102.8°, but upon the following day dropped to 99.2° and rose on the same day to 101.8° and assumed the characteristic type until October 2d, when it fell gradually to nearly normal. The patient now seemed quite bright; her pulse was 100, and the case appeared to be one of only moderate severity. On October 6th the temperature again rose to 103.4° and the pulse became more rapid (132–144). Cardiac stimulants were ordered and patient did well until October 11th, the twenty-first day of her illness (according to her statement), when erysipelas began upon the bridge of the nose, and extending rapidly on both sides of the face,

[1] Read at the Meeting of the Cook County Hospital Clinical Society of Chicago, November 5, 1891.

assumed a butterfly form with sharply outlined margins. She seemed very stupid and dull, the lips cyanotic, the face and hands pale and cold, the respiration rapid (40), the pulse 144, weak and irregular. With the appearance of the erysipelas a sudden change had occurred. The patient was transferred to an isolation-ward, placed under the care of a special nurse experienced in the care of this class of cases and given cardiac stimulants; nourishment was given by the mouth and rectum. Tr. ferri chlor. ♏xv, every four hours, and the application of a 10 per cent. solution of ichthyol to the face were ordered. The patient's condition, however, rapidly became worse, and she died on October 14th, having been delirious, with rapid respiration and frequent pulse, and constant involuntary muscular twitching prior to death.

CASE IV.—The fourth case occurred eight days after the preceding, upon the twenty-second day of the patient's illness, following shortly after several attacks of epistaxis and constant picking at the nose.

J. P., a Swede, thirty-eight years of age, was admitted to the ward October 4, 1891, with a temperature of 104°, and marked involuntary twitchings of the muscles of the face and hands. He presented all the objective symptoms of typhoid fever. His tongue was very dry and coated with brown sordes, and there was a busy, muttering delirium. He was ordered resorcin as an intestinal antiseptic, with the addition of quinine and strychnine, and he was placed upon typhoid orders. Within three days his temperature dropped to 96° (axilla) (the reason for this being unascertainable), and remained at 101.2° until October 15th, when the patient seemed very bright, with tongue quite clear; the temperature became normal, with the pulse 96. With the aid of an interpreter the patient was able to state that he had been ill seven days prior to admission and had had typical prodromal and early symptoms. Convalescence seemed to have begun—the good effect being ascribed to the resorcin, when upon October 17th he had one slight and two severe attacks of epistaxis. He did not seem as rational, and he was constantly picking at the nose with his fingers. Upon the evening of October 18th the temperature suddenly rose to 101.5° (axilla). No cause for this rise could be found, but upon the following morning the man was quite delirious, the pulse 120, weak and irregular. A well-defined erysipelatous swelling was now present upon both sides of the face and nose and upon the upper lip. It was estimated that this must be the twenty-second day of his illness. He was immediately transferred to the isolation-ward. Cardiac stimulants, tr. ferri chlor. ♏xxx, every four hours, and constant application of wet boric acid dressings were ordered. The respiration was shallow and rapid; there was marked delirium; the pulse was 120, weak and irregular; and death took place October 20th—thirty-six hours after the first recognition of the disease.

Although the mortality-rate in the cases reported is very high, we feel confident that everything possible was done in order to save them. Experienced nurses, prompt recognition and medication were employed.

According to Liebermeister in his exhaustive article upon "Typhoid Fever" in *Ziemssen's Cyclopedia*, erysipelas as a complication generally occurs during convalescence and rarely at the height of the disease; the complication may be a dangerous factor.

Of 1420 cases of typhoid fever seen at Basle, erysipelas appeared in ten cases, all of which recovered. In other words, the complication occurred in a little less than one per cent of the cases.

In our own hospital, in 1200 cases occurring in the regular wards since 1888, there are records of two cases, one of which recovered, while the result in the other case is not mentioned, so that we have had six cases in 1200, or one-half of one per cent. Gerente, quoted by Hare and Patek in their article upon "Rare Complications of Typhoid Fever,"[1] has found, including Liebermeister's, that erysipelas occurred in sixty-four cases of 3910, or nearly 2 per cent. He has also found that it is most frequent in the grave adynamic forms of typhoid and in those of long duration. It shows itself especially, and almost exclusively, during the last period and during convalescence, as in my cases. According to Gerente, it produces a marked amelioration of the symptoms, but with this statement I cannot agree, as in all of our cases it caused a most decided change for the worse, and almost immediately increased the gravity of the prognosis. Gerente also states that the appearance of facial erysipelas in typhoid is of grave prognosis (sixteen deaths among thirty-six cases), the gravity lying less in the erysipelas than in the poor general condition of the patient.

The question as to the path by which the germs gain entrance has been much discussed. According to Griesinger, they enter by means of an inflammation of the frontal or sphenoidal sinuses and also when ulceration of the buccal mucous membrane exists. In the foregoing cases it seems quite plausible that the germs should have gained entrance by the abraded surfaces caused by the constant picking at the nose after the epistaxis in the first, second, and fourth cases. In none of these was there any visible buccal ulceration or any stomatitis.

Unfortunately, at the time of the occurrence of these cases we were unable to make any cultures from any fluid removed. Whether the streptococcus erysipelatosus of Fehleisen is the cause of the erysipelas complicating typhoid is doubtful in some cases, for Rheiner[2] was unable to find the germ in two cases of gangrenous erysipelas following typhoid. In these he found bacilli which he believed

[1] THE MEDICAL NEWS, June 20, 1891.

[2] Rheiner: "Beiträge zur pathologischen Anatomie des Erysipels bei Gelegenheit der Typhus-Epidemie in Zürich, 1884." Virchow's Archiv, Band c, S. 185.

were identical with the Klebs-Eberth bacillus of typhoid. Hare and Patek found the streptococcus of Fehleisen in some serum removed from one of their cases.

In regard to the treatment there is little to be said. A number of specifics have been recommended. The erysipelas in these cases of typhoid is of short duration, and the first indication is to stimulate. Camphor is especially recommended. Hot antiseptic compresses or painting the parts constantly with ichthyol complete our present therapeutic measures.

THE RECENT INVENTIONS OF NEW OPTICAL GLASS.

BY C. A. SIEGFRIED,
U. S. NAVAL TRAINING STATION, NEWPORT, R. I.

THE microscope is chief among delicate optical instruments, and "what it has accomplished constitutes the glory of the natural sciences." Since the discovery of the compound microscope in Holland, about 300 years ago, it has passed from the workshop of the spectacle-makers to the hands of the trained optician, where it has undergone, by successive gradual steps, those corrections and improvements that we see in the instrument of to-day. Transmitted light was first used in 1685, the reflecting illuminating mirror in 1715, and the greatest of all improvements—the achromatic and aplanatic objectives—in 1824. Bacteriologic study must be credited with a great share of the more recent advances, for in this work the constant endeavor is to see further and finer in the search for the physiologic and morphologic structure of the ultimate protoplasmic bodies or cells of all living tissues.

Up to the beginning of the last decade it may be said that the limit of performance had been reached, with the lenses in use, composed of the ordinary crown and flint glasses, taking into account the best individual management and technique—the most important element of success in microscopy. Faraday, Ross, and a clergyman named Harcourt, in England, Chevalier in Paris, Amice in Italy, Fraunhöfer in Germany, and other less well-known men, had years ago produced new and improved glass and lenses; but impermanency of external surface, due to instability of the elements of the glass, proved an insurmountable obstacle to its general use, as also the enormous attendant expense of further investigation and production. It came to be universally felt that if we were to advance further in the study and knowledge of the infinitely little, in all branches of natural science, in biology and medicine particularly, and in view of the fact that the limit of perfection regarding the management of spherical and chromatic aberration had been reached, new glass must be produced. The history of previous attempts in this field was of much value. Bodies of lower refractive indices were known, such as the diamond and other precious stones, but, for various reasons, the employment of these was impracticable; but fluor-spar or fluorite, having both a low-color dispersion and a low refractive index, was taken up, and objectives of vastly improved qualities produced. This mineral, found native in the Bernese Alps in Switzerland, offered great convenience in the choice of kinds of glass to be used in obtaining perfect compensating effects for the removal of chromatic and spherical aberrations, and neutralizing subsidiary effects in lens systems. But it was soon discovered that fluor-spar could not be obtained in the quantity and of the quality desired, and attention fortunately was now turned solely to the laboratory.

It was here that the Prussian government stepped in, and with a grant of 60,000 marks ($15,000) the experimental stage of the work was begun in Jena, about ten years ago, under the direction of Drs. Abbe and Schott, and their associates in physics and chemistry. In two and a half years the chief practical work of the investigation was effected, and they succeeded in determining experimentally the mutual relations of optical effect and chemical composition, for all possible amorphous compounds produced by solidification after fusion. A whole year was spent in collecting data, on which it was predicted that a systematic investigation of the question of glass-smelting would lead to an advance in practical optics.

The impossibility of getting rid of the chromatic differences of spherical aberration is dependent on the fact that, with the crown and flint glass formerly used, the dispersion always goes hand-in-hand with the mean refractive index, so that the higher dispersion always belongs to the higher index, and *vice versa*. The aberration would be completely, or at least approximately, compensated, if we possessed materials in which a relatively low refractive index was combined with a high dispersion, or a high refractive index with a relatively slight dispersion. It would thus be possible, by a suitable combination of such a material with the ordinary crown and flint glass, to remove the chromatic and spherical aberration independently of one another, and thus to fulfil the essential condition on which the removal of the chromatic difference depends. The perfecting of delicate optical instruments appeared, therefore, to depend on an advance in the art of glass-smelting, so that it should be possible to produce glasses, suitable for the removal of the secondary spectrum, in which dispersion and mean refractive index would be differently related than in the glasses then in use.

The uniformity in optical properties that char-

acterizes most kinds of glass is due to the small number of materials used in their manufacture, viz., silica, alkalies, limestone, lead, and, in lesser degree, clay and thallium. The great aim was to advance beyond these narrow limits; and, directed by a methodical study of the optical characters of various chemical elements, the investigators used such as appeared suitable to the end in view. They had to produce a glass free of foreign matter, and with a not too strong action on the walls of the containing vessel; to be kept homogeneous by energetic stirring while in the molten state, so that it would be free from striæ of refractive indices different from that of the main mass; free of cloudiness, crystal-formation, and blisters, in melting and cooling; to bear reheating to the melting-point without cloudiness or crystal-separation; kept free from strains by suitable process of cooling; it must offer sufficient resistance to atmospheric agencies, and must show no signs of hygroscopic properties; be colorless; and of sufficient hardness to allow of grinding, polishing, and shaping of the refractive surfaces.

Only relatively few inorganic anhydrides give rise to amorphous bodies when fused with certain metallic oxides and cooled. Hitherto, silica was the only one that answered the requirements named, but boric, phosphoric, and arsenic acids were known to yield glass-like bodies in certain of their compounds. The fusions of phosphoric and boric acids with a great number of metallic oxides, working with small porcelain crucibles and laboratory blow-pipe, yielded, after many failures, glasses of extraordinary variety, and thus showed that considerable gradations in refractive index and dispersion could be obtained by their use. Finally, after long and wearisome labor, samples of glass weighing upward of 25 kgm. were obtained, large enough for all practical and scientific purposes. By these the optical characters of a large number of metallic oxides were soon recognized, and it was found possible to incorporate in the glass, in quantities above 10 per cent., twenty-eight other bodies, besides the five hitherto used. There were: Boron, phosphorus, lithium, magnesium, zinc, cadmium, barium, strontium, aluminium, beryllium, iron, manganese, cerium, didymium, erbium, silver, mercury, thallium, bismuth, antimony, arsenic, molybdenum, niobium, tungsten, tin, titanium, uranium, and fluorine.

The first object of the investigation—the power of obtaining gradations in refraction and dispersion—was thus attained. For the removal of the secondary spectrum, however, only comparatively few elements were found to offer suitable variations from the ordinary course of the dispersion. Of these, boric acid produced a contraction of the blue and a widening of the red extremity of the spectrum, while fluorine, potassium, and sodium had an opposite effect. For all other elements the course of the dispersion was the same as with silicate glass. Accordingly, since the ordinary flint glass shows an extension of the blue extremity of the spectrum as compared with crown glass, as high a percentage of boric acid as possible must be incorporated with it in order to obtain a perfect compensating effect. Thus boric acid has become the fundamental constituent of all flint glasses destined to diminish the secondary spectrum. The conditions are less favorable when it is desired to effect the compensation by widening the blue extremity of the spectrum of a crown glass. Of the three elements—fluorine, potassium, and sodium—suitable for this purpose, the last only can be introduced into silicate glass in very small quantities, and the potassium in quantities not exceeding 25–30 per cent.; this because of their hygroscopic effect.

The chief characteristic of phosphoric acid—that of yielding glasses of comparatively slight dispersion, with high refractive index—was made use of to solve this problem, for it had been found that, with equal ratio of refraction and dispersion, glasses of higher refractive index showed an extension of the blue extremity of the spectrum. Thus, by the use of phosphoric acid for the crown glass, and a glass containing a high percentage of boric acid for the flint, it was found possible to almost completely remove the secondary spectrum.

While introducing material to produce certain optical effects, an important point to be considered was the modification of the composition of the glass, so that its external character should remain satisfactory. With phosphates and borates the alkalies must be used sparingly, or deterioration of the polished surfaces of lenses under the influence of the atmosphere is unavoidable. It was ascertained, however, that certain glasses, in themselves hygroscopic, could be made serviceable by the introduction of large percentages of clay, zinc oxide, or other compounds, but with the greatest accuracy, otherwise partial or complete crystallization ensued. On this ground many of the possible borate and phosphate glasses had to be excluded. However, a series of phosphate and borate glasses were produced. For the phosphate, magnesia, clay, and potash offered the least resistance, so that a crown glass could be produced with dispersion far less than that seen in any yet made. The use of baryta with phosphoric acid in a crown glass caused a decrease of refractive index, and at same time a lower dispersion. An aluminium-sodium-baryta-borate gave a borate crown glass, the ray-path of which is useful for many purposes. The borate flint glasses, containing as much 50 per cent. of boric acid, were made by the addition of clay, zinc oxide, and barium

oxide, to satisfy all requirements, and to show no sign of hygroscopic characters.

The problem of the removal of the secondary spectrum having been satisfactorily settled by the production of the phosphate and borate glasses, attention was now directed to the improvement of the ordinary silicate glass in common use. By the introduction of boric acid, zinc ozide, magnesia, baryta, and clay, silicate crown and light flint glasses were obtained with very varied relations of refraction and dispersion. These combinations are found to be of great service in aplanatic constructions for photographic purposes, for, owing to their increased transparency for the chemically active rays and their slight dispersion, they give plane and sharp images in the camera.

Dr. Schott's experience with "Hart" glass, some years preceding this investigation, proved valuable when the problem of cooling, and the effect of strain, came to be considered. By experiment he had proved that the hardening of glass proceeds inward, layer by layer, and this induces a state of strain, manifesting itself by diminished specific gravity and the phenomena of double refraction. These excentric strains are especially harmful in lenses, as the focal length varies in different parts, as if it were cut irregularly in the direction of the strain. Finally, the molten contents of the thick copper cauldrons were cooled so gradually that a fall of ninety-five degrees of temperature extended over periods as long as four weeks, the large gas flame being connected with a mercury vapor pressure thermometer, both regulating the flame and marking the temperature. It became necessary to construct complicated and unusual apparatus for the production of the glass in large quantities. For making borate glass, platinum crucibles and stirrers with rotary and up-and-down motions became necessary. Corrosion of containing vessels, cooling of surface, and formation of air-bubbles and striæ in cooling, had all to be overcome.

Coming now to the practical benefits, the result already realized from these improvements and inventions is that while microscopically we could distinguish objects in the approximate form of circles or squares of a diameter of $\frac{1}{100000}$ of an inch, we now distinguish them if 125,000 to the inch. Yet this may make the difference between tracing definitely some part of the life history of a microorganism, or failing to trace it. There is still on this side of the ocean a doubt as to the stability and durability of the new glass, and the new "apochromatic" objectives made from it. Some of the first objectives from the workshops of the leading opticians in Germany have been returned for the removal of external surface defects—probably of a hygroscopic character—due in ordinary use to extreme sensitiveness and chemical action from atmospheric exposure. But the later objectives are more stable, and are coming into more extended use when it is desired to attain the highest results in biologic study. There is no longer just reason for denying the superior qualities of these new lenses for definition and management of light and color. For the average worker in biology and pathology, the best lenses of superior crown and flint glasses, in skilful combination, by trustworthy makers, are sufficiently satisfactory for all practical purposes, the cost being also not over a third of the newer apochromatic objectives. As time goes on, improved systems and combinations of lenses are constantly being invented, much use being made of the older crowns and flints combined with the new glass in the same system; and, with the increasing technical skill in smelting, and a better appreciation of the physics of optics, for which the Germans must be given the chief credit, the cost will in all probability, in the near future, be placed within the means of all those workers desiring these improved "oculars" and "objectives." The number of the varieties and kinds of glass used for optical purposes is now upward of sixty-six, and additions to the list are frequently reported. The microscope is no longer a toy, nor is its use solely relegated to laboratory workers, but it has become an essential part of the modern properly equipped and successful physician (successful in appreciating the character of disease); of the workers in all branches of natural science; for detecting adulterations in foods, in water, in fabrics, the forging of documents and the imitations of handwriting; in fact, this instrument is of the first importance in all later educational and scientific work. When we reflect upon the advance in scientific procedures in recent times by means of spectroscopes, telescopes, and the various optical instruments now in general use, and their extraordinary improvement within the last decade, the character of the advance in our knowledge of glass-making is better appreciated.

Prescribing Opticians.—According to a decision recently given by a judicial authority at Havre, an optician who gives a patient advice as to the condition of his eyes, and prescribes glasses to remedy defective vision, is guilty (according to French law) of the illegal practice of medicine just as if he had ordered remedies or given medical advice without possessing a diploma recognized by the law.

LEGISLATION IN PENNSYLVANIA ON MEDICAL AND HEALTH MATTERS DURING THE SESSION OF 1891.

By HENRY A. RILEY, A.B., LL.B.,
OF NEW YORK.

THE special subject attracting the attention of the profession prior to and during the late session was the passage of some act regulating the examination of applicants for medical practice. Several bills were prepared and earnestly advocated, but no law was passed, and the struggle will no doubt be started again when the Legislature meets next year.

An important law was enacted, providing for an Asylum for the Chronic Insane. A board of five commissioners was authorized to be appointed by the Governor to select a site and erect the buildings. The site was to be convenient to the other asylums for the insane, and to contain not less than five hundred acres of land. The cost of the land and buildings was not to exceed $500,000, and the plans for the buildings were to be approved by the Board of Public Charities. The time for erecting the buildings was fixed at three years, and when finished they were to be turned over to a permanent board of nine trustees. The asylum is to be wholly devoted to the chronic insane, and persons who have been insane for any period less than a year are not eligible for admission.

A commission of five persons, including the Governor, was authorized to select a site for a quarantine station on the Delaware River, remote from the centers of population.

It was also authorized to inquire into the feasibility of a joint quarantine for the protection of all parts of the Delaware River and Bay, to be controlled by the several States bordering thereon. A report was directed to be made to the next Legislature.

An appropriation of $383,852.02 was made to repay the amount placed in the hands of Governor James A. Beaver by the People's Bank of Philadelphia and William H. Kemble, to meet the expenses incurred by the Johnstown flood. This amount was loaned without interest, and entirely on the promise of Governor Beaver to use all honorable means to procure the repayment by the State when the Legislature should meet.

The general run of decisions in the various States has been to the effect that bequests for the care of graves are void if made in perpetuity, as not being for a charitable use. The Legislature, however, passed two laws on the subject, which are certainly of importance and interest. One declared that property left for the care and maintenance of cemeteries and graveyards, or for graves and monuments therein, or for erecting the same, shall be deemed to be left for a charitable use, and shall not be void on the ground of tying up property in perpetuity.

The other law allowed incorporated cemetery companies to accept, by deed or will, devises or bequests in trust for the care and decoration of family burial lots, vaults, or graves, provided the cemetery companies report to the Court of Common Pleas of the county, and obtain the approval of the court to the investment of the principal sum of the bequests.

A very elaborate and detailed law for the proper management and working of coal-mines, so as to secure the best protection for miners, was passed, after having been considered and approved by a commission consisting of mine inspectors, mine-owners, and practical miners. Some of the provisions of the law are as follows: The anthracite coal-fields are divided into eight inspection districts, with an inspector at the head of each. The inspectors are appointed by a board of examiners consisting of five members, three of whom are practical coal-miners, and two reputable mining engineers.

The salary of each inspector is $3000, and he is required to visit the collieries in his district as often as his duties will permit, or exigency requires, and he must see that every necessary precaution is taken to secure safety.

He must visit the scene of every accident, for the purpose of examining into the particulars, and attend all inquests on the bodies of persons killed at the mines.

An annual report is to be made to the Secretary of Internal Affairs, enumerating accidents, the condition of workings, ventilation, etc. The inspectors have the right to enter any mine, either by day or night, and must be supplied with accurate maps of the mines by the owners.

There must be two openings from each vein or seam of coal, for safe and distinct means of ingress and egress.

Mine-owners shall provide at the collieries an ambulance with two stretchers, for the purpose of conveying to his home or to a hospital any person injured. The ambulance must be provided with easy springs, bedding, spring mattresses, etc.

No boy under fourteen is allowed to work in a coal mine, and no woman or girl of any age. Boys under twelve cannot be employed in the outside workings.

A considerable portion of the law is taken up with detailed directions for ventilation and the regulation of blasts. Ventilating currents must be forced along the face of workings in sufficient volume to sweep away smoke and noxious gases. Inlet and outlet passages are to be separate. Doors must open automatically, and main doors must have an atten-

dant. In mines generating explosive gases, the foreman must examine, every morning, all working places to see if they are safe.

In cases of accident resulting in death, the inspector may notify the coroner to hold an inquest, if he deems it necessary.

If the inspector finds anything about a colliery defective or dangerous, he must give written notice to the mine-owners to remedy it. If the owners object to the carrying out of the notice, they can demand a board of arbitration, which shall within forty-eight hours decide the matters submitted to them.

If the owners or superintendent are negligent, and persist in refusing to carry out reforms demanded, they are liable to a fine of $500, and imprisonment not to exceed three months.

It is said that the crematory at Pittsburg has incinerated more bodies than any other in the United States, and it is not surprising that the Legislature passed a law requiring that before every cremation a permit shall be obtained from the Board of Health or local health authorities. Before this permit is issued the physician or coroner must file a written certificate, giving all the facts of death and the usual statistics.

The dairy and cattle interests were favored by a supplemental act, requiring all imitations of lard to be labelled "Compound Lard," in letters half an inch long. The penalty was fixed at $50 for the first offence, and $100 for subsequent offences.

The Pharmacy Law was amended so as to permit the legal representatives of a deceased registered pharmacist to carry on the business under the charge of a qualified and registered assistant.

The usual large appropriations were made for the State hospitals and public institutions, and many special bills were passed for permanent improvements, and for aiding in the establishment of new institutions. A good many appropriations were, however, vetoed by Governor Pattison, either on the ground that they were in excess of the amounts recommended by the Board of Public Charities, or had not been recommended at all. A further ground of disapproval in some cases was that the institutions were not under the control of the State. Some of the appropriations are of general interest, and are as follows: $14,650 was appropriated for cottages and maintenance at the Bituminous Coal Hospital, at Connellsville, and $13,000 for the same purposes at the Philipsburg Hospital; $15,000 was appropriated for erecting and furnishing the Chester Hospital, at Chester, provided $5,000 was raised by private subscription, and a site given worth, at least, $4,500; $12,500 was given the Shenango Valley Hospital, at New Castle, for erecting and furnishing new buildings, provided $10,000 be raised and paid into the treasury of the hospital by private subscription; $10,000 was appropriated to the Pottstown Hospital and Dispensary for new buildings, on the condition that suitable grounds be secured, and $10,000 raised by private subscription; the Carbondale Hospital Association received $10,000 for new buildings on the condition that a similar sum be raised by private subscription. The Pittston Hospital Association was to receive $15,000 for construction and furnishing, provided the Association should be legally incorporated, and the treasurer give a bond. Further conditions were also made that a site of not less than three acres be secured, and $5,000 subscribed by private persons. Some of the public institutions received appropriations for new buildings, etc. The Pennsylvania State Lunatic Asylum, at Harrisburg, was granted $20,000 for the purchase of additional land, and $10,000 for a lighting plant. The University of Pennsylvania received $20,000 for the extension and betterment of buildings for hospital purposes. The Williamsport Hospital was given $10,000 a year for two years, provided no distinction was made in the admission of patients, on account of color, nativity, or religion. The Homeopathic Medical and Surgical Hospital and Dispensary, at Pittsburg, received $15,636.52 for a deficiency, and $15,000 a year for two years, on condition that ten free beds be maintained, to be occupied by persons recommended by the Mayor or Poor Board; $12,500 was appropriated for the completion and furnishing of an infirmary at the Pennsylvania Training School for Feeble-minded Children, at Elwyn, and $12,500 for new buildings for feeble-minded girls afflicted with epilepsy; $15,000 was appropriated for building a home for the training of deaf children before they reach school age, and a commission of two persons was appointed to select a site and prepare plans, etc.

ORIGINAL LECTURE.

POLIOMYELITIS.

A Clinical Lecture delivered at the Arapahoe County Hospital, October 24, 1891.

BY J. T. ESKRIDGE, M.D.,
NEUROLOGIST TO THE ARAPAHOE COUNTY, ST. LUKE'S, AND DEACONESS HOSPITALS, DENVER, COLORADO.

GENTLEMEN: The case I wish to study with you today presents a feature of especial interest on account of the new diagnostic point between multiple neuritis and poliomyelitis that is beautifully illustrated:

A. I., twenty-two years of age, an expressman for the past five years, has suffered with paralysis of the left arm during the last four or five weeks. His family history is unimportant. His health was always good until the present illness. He has indulged only occasionally in alcohol. He suffered with two venereal sores in 1888, and had gonorrhea in 1889. He denies over-indulgence in venereal habits. Five weeks ago he began to feel

pain in the left elbow and shoulder. The pain was sharp at times, especially at night, but usually it was dull in character. The pain has remained about the same up to the present time. He has simply a sore feeling just above the elbow and in the shoulder. There are no shooting pains or numb sensations. He has suffered with pains in the back of the neck, but only for the last few days. These post-cervical pains first developed nearly five weeks after the beginning of the shoulder pain. Shortly after the first appearance of pain in the arm he noticed that it was difficult for him to use the part, but he is unable to say whether the loss of power was entirely due to paralysis of the muscles or partially caused by the pain felt on trying to move the extremity. He had no difficulty at the time in using the left forearm and hand, so that he feels certain that the loss of power was above the elbow. He consulted a physician at that time, who, without an examination of the arm, diagnosticated rheumatism and treated him for it. Subsequently, he presented himself at the clinic of the Arapahoe County Hospital, and Dr. Baker, suspecting neuritis and failing to make a diagnosis satisfactorily to himself, brought the patient to me. I made a careful examination at that time, and as his symptoms differ but little to-day from what I then found them to be, I shall ask you to study the case with me as I make the examination before you. The history, to state it succinctly, is pain, without apparent cause, beginning in the left shoulder and elbow, with some pain in the arm above the elbow, loss of motion coming on at about the same time and involving the muscles of the upper arm and shoulder, extending over a period of about five weeks.

Examination shows that there are no symptoms of ataxia in the legs, the knee-jerks are normal, and there is no ankle-clonus. The muscles of the lower limbs are well preserved and fairly strong. The dynamometer registers: right, 128; left, 88. The muscles of the right arm are quite strong. He is unable to abduct the left arm from the chest, owing to complete paralysis of the deltoid, but he can swing the arm backward or forward, bend and extend the arm at the elbow, and open and shut the hand with considerable force. All the muscles below the elbow seem to be in nearly a normal condition. The biceps and triceps are fairly strong; the deltoid is the only muscle that is completely paralyzed. There is partial paralysis of the trapezius, pectoralis major, and serratus. The last three muscles are considerably wasted, but not as markedly so as the deltoid. Measurements: Right forearm, 9⅛ inches; left, 8⅞; upper arm in contraction, right, 10⅛; left, 8¾; over the deltoid high up in the axillary space, right, 10¾; left, 8¾. Reflexes of the left forearm, normal; but of the deltoid, biceps, and triceps, absent. Tactile sense is normal throughout the arm and hand; neither are there spots of tenderness anywhere over the arm, although the patient complains of pain in various portions of the arm. When the muscles are relaxed, the joints, especially those of the elbow and shoulder, can be moved freely without giving rise to the least pain. He complains of considerable pain in the shoulder, but no tender spots can be found on pressure, and the muscles that seem to be the seat of pain contract without giving rise to discom fort

One point to which I wish to direct your attention especially is the action of the pectoralis major muscle. You are aware, from your anatomic studies, that this muscle is composed of two parts, the superior or clavicular fibers and the inferior or sternal fibers. When the arm is held in the horizontal position in front of the chest the superior portion of the muscle aids in further elevating the arm or in maintaining the arm in that position when weights are held in the hand. This portion of the muscle, when it acts alone, is an elevator of the humerus. When any resistance is offered to the arm in its descent from the elevated position, the inferior fibers of the great pectoral muscle contract and enable it to overcome this resistance, so that the lower portion of the muscle when acting alone is a depressor of the humerus. Now, if I take this man's right arm, which is strong and healthy, and abduct it from the side to the horizontal position, carry it forward until it is about at right angles with the front of the chest, and then request him voluntarily to carry the arm in front of the chest, you notice the superior fibers of the pectoralis major contract and carry the arm to this position. If, now, I resist the arm in this movement and request the patient to exert force to overcome the resistance, you see that the inferior and superior fibers come out prominently in contraction to enable the arm to overcome the resistance; so that we find when the superior and inferior fibers of this muscle act separately, one set elevates the humerus and the other depresses it, but when they act in association with each other they have one function in common, and carry the arm across the front of the chest. Now, let us study the action of this muscle on the affected side. On elevating the left arm to the horizontal position and bringing it to a point about midway between the lateral and anterior aspects of the chest, I request the man to further elevate the arm. He makes an effort, but there is no contraction of the superior fibers of the pectoralis major. While holding the arm in this position, I request him to depress it and immediately the inferior fibers come out in vigorous contraction and depress the arm with considerable force. On returning the arm to the position from which the inferior fibers have just depressed it, I now carry the arm a little more in front of the chest and request him to bring the arm across the front of the chest, and at the same time I offer slight resistance to this movement. In overcoming this resistance the superior and inferior fibers of the pectoralis major contract quite vigorously to bring the arm into the suggested position. You observe, then, that while the superior fibers are unable to contract in efforts to elevate the arm beyond the horizontal position, they act quite vigorously in association with the inferior fibers in carrying the arm across the front of the chest, so that we find the superior fibers of this muscle paralyzed for one movement and not for another. Now, what is the significance of this form of paralysis? Dr. Beevor, of England, in an article published in a recent number of *Brain*, claims that this form of paralysis in all probability can only be caused by lesions in the spinal cord or its nerve-roots, and not by a lesion in the brain or nerves. If these statements set forth by Dr. Beevor are proved by subsequent observation to be correct, they will become of very great importance in differentiating certain lesions of the nerves from lesions of the spinal cord.

We will endeavor now to make a diagnosis by exclusion, to see where we can locate the lesion in this case. With the history that this man gives, the first lesion suggested is neuritis. The pain of which he has complained from the first until the present, and the weakness of the arms, point to this condition. This view is still further strengthened by the fact that he was compelled in his daily occupation to lift heavy weights and carry them on his shoulder, which might have bruised the circumflex nerve, which, you know, supplies the deltoid, the muscle most affected in this case. The points that most militate against this view are the absence of tenderness and the preservation of sensation at all parts of the arm and shoulder. One of the most prominent symptoms in acute inflammation of nerves is sensitiveness of the nerve and of the muscle supplied by the nerve. Further, if this nerve were sufficiently injured to cause absolute paralysis of the deltoid, sensation would be affected in the cutaneous distribution of the nerve; but this we find not to be the case. There is no disturbance in any portion of the arm or shoulder in any form of sensation. Again, the pectoralis major muscle is supplied by two nerves—the internal and external anterior thoracic. These would not likely be injured in contusions involving the circumflex. And yet, again, it is hard to conceive that the lesion of the nerves resulting in paralysis would affect the muscle for one movement and not for another. Theoretically, at least, we would expect that nerve-lesions would affect to a greater or less extent all of the muscular fibers supplied by the injured nerves. It seems to me that we can exclude neuritis in this case.

From the absence of any history of cerebral symptoms, such as headache, ocular disturbances, affection of the facial muscles, either by occasional spasms or paresis, and the absence of any twitching of the muscles of the arm, and the limitation of the paralysis to half of the muscles at the shoulder, we are enabled to exclude brain-lesion.

The acuteness of the trouble makes it unnecessary to consider any of the chronic wasting diseases affecting the muscles by paralysis. We have left, then, but the spinal cord in which to place the lesion. In the absence of any sensory phenomena we are justified in concluding that the trouble is located in the cells of the left anterior cornua of the cord. As the deltoid, the muscle most affected, yet responds to a strong faradic current, the prognosis is good.

The treatment will consist of massage, electricity, and of strychnine, combined with a good nutritious diet. As the muscles respond to the faradic current, we will have this current applied, with slow interruptions, to the muscles for ten or fifteen minutes each day. We will have the muscles of the arm thoroughly manipulated once daily. Strychnine may be given by the mouth or hypodermatically. We will first try it by the mouth, beginning with $\frac{1}{30}$ of a grain before each meal, gradually increasing to $\frac{1}{18}$ or $\frac{1}{12}$ three times daily. If improvement after a while should cease, I will then direct $\frac{1}{24}$ of a grain to be injected into the deltoid muscle once daily. I have employed the hypodermatic method of using strychnine with very satisfactory results in certain cases of paralysis, and frequently have given $\frac{1}{10}$ of a grain daily, but such a quantity should not be given until the dose is gradually increased, so that the patient will bear it without any unpleasant effects.

CLINICAL MEMORANDA.

A UNIQUE CASE OF RICKETS WITH SYNCHRONOUS HEART-CONTRACTIONS AND INSPIRATORY ACTS, EACH 54 PER MINUTE.

By C. W. LEIGH, M.D.,
FORMERLY HOUSE SURGEON AND INSTRUCTOR IN CHICAGO POLYCLINIC; CAPTAIN AND ASSISTANT SURGEON, SECOND INFANTRY, I. N. G., CHICAGO, ILLINOIS.

THE patient, a male child, two years and two months old, suffered, as the mother stated, with shortness of breath; it was not disposed to play or exercise; it was mentally somewhat dull, although possessing a bright, intelligent face. It was easily frightened, did not have much appetite, drank water liberally during the night, and after doing so frequently coughed severely and then vomited. He had been constipated since birth, and had a habit of scratching or picking his nose; he had also cold sweats, and worried and cried during the night-time. In the third month of his life umbilical hernia appeared which had about disappeared at the time of the first examination.

Upon examination, the child was found plump in form and well nourished; the face somewhat pale, but intelligent in expression; the hair a very light yellow—almost white; the eyes blue. The head was large, the forehead somewhat projecting, as in rickets. Both anterior and posterior fontanels were open. There was no tabes cranii. The eyes were large, somewhat prominent, and the pupils normal. The mouth emitted a fetid odor due to badly decayed teeth and suppurating gums. There were no Hutchinson teeth. The roof of the mouth was highly arched. On the chest and abdomen, especially on the sides, there were some slightly enlarged veins. The middle dorsal vertebræ were slightly prominent; this prominence was not due to Pott's disease, as movement was perfectly free, and pressure from above downward or from behind forward caused no pain. There was a marked constriction of the ribs in front, extending from the fourth to the seventh. The prominence of the cartilages (Rosencranz) was marked in the upper ribs. The knee-joints were slightly enlarged, but the other joints were normal.

The apex-beat of the heart could be felt at the lower border of the tenth rib and a half-inch to the left of the nipple. The heart boundaries were: upon the right side, the inner border of the sternum; superiorly, the fourth intercostal space; and externally, the mammillary line. The tricuspid sound of the heart was absolutely normal and distinct; the mitral was also normal, but not so distinct; the aortic could not be heard on account of the exaggerated respiratory murmur. The pulmonary second sound only could be heard. There were no heart-murmurs. The pulse was 54 per minute.

Normal bronchial breathing could be heard over the entire chest, except that it was exaggerated. The percussion note was normal. The respirations numbered 54 per minute.

The spleen seemed somewhat enlarged; however, the apparent enlargement may have been due to downward displacement caused by chest constriction. The liver-dulness commenced at the sixth rib. There was no evidence of any pathologic condition of the kidneys.

The mother of the child is a native of Germany, forty-three years old, large, and somewhat fleshy. She states she has always been healthy, except for a period of time during her youth, when she was troubled considerably with sore-throat, and at the age of fourteen she had a "nervous fever," from which she lost her hair. She never had a skin-eruption, and there are no symptoms of tuberculosis. She has given birth to twelve children. The first lived five days; the second, four months; the third, three months; the fourth and the fifth are living and in perfect health; the sixth lived six months; the seventh was born dead at term; the eighth was born dead; the ninth is living and in fair health; the tenth was born dead; the eleventh is living, and the twelfth is our patient.

The father is also a German, fifty-three years of age; he is small and slight in stature and weak. He has had three attacks of inflammation of the lungs; he has never had sore-throat, loss of hair, skin-eruption, or any other symptom of syphilis.

The very remarkable and interesting point to be observed in this case is that the heart-contractions and the inspiratory acts are absolutely synchronous, each 54 a minute—a very rapid respiration and a very slow pulse. I have searched the literature in vain for a similar case, and I am convinced that it is the only one of its kind on record.

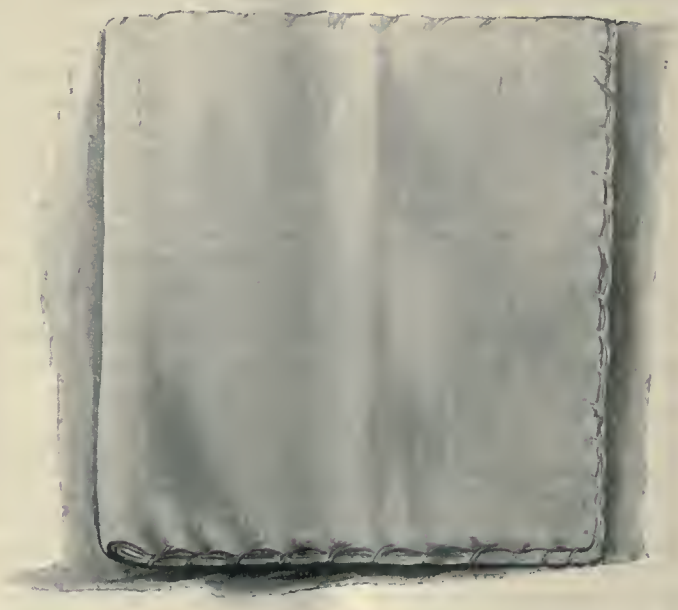
The child was presented to me in the summer of 1888, during my service at the Chicago Polyclinic. He remained in the same condition until his death, which occurred in July, 1890, at a time when I was absent from the city on a vacation. The parents state that he was suddenly seized with a "fit," which was rapidly followed by others, and death resulted in less than three hours. Unfortunately, no post-mortem examination was made; whether it would have furnished an explanation of the singular pathologic condition is, of course, a question.

PADS OF ABSORBENT GAUZE AS A SUBSTITUTE FOR FLAT SPONGES IN ABDOMINAL SURGERY.

BY WILLIAM EASTERLY ASHTON, M.D.,
GYNECOLOGIST TO THE PHILADELPHIA HOSPITAL.

IN this era of surgical progress, when success so much depends upon technique and care, the aim of all operators must be to render their operations as simple as is conformable with the well-defined and strict laws of asepsis. With this object in mind, I desire to call attention to gauze pads as a substitute for flat sponges in all forms of abdominal and pelvic surgery.

The pads are made of the ordinary unsized absorbent gauze in use in all hospitals for surgical dressings. I employ two sizes: a large pad, 9 inches square, which is used in abdominal work, and a small one, 4½ inches square, for pelvic cases. Each pad is composed of sixteen layers of gauze, folded together in such a manner that the edges cannot fray. The large pad is made as follows: A single layer of gauze a yard square is folded at each extremity upon itself, so that the folds meet at the middle. This makes two layers of gauze, oblong in shape, the extremites of which are now folded over so that they meet in the midle. There are now four layers and the shape of the pad is square. This is then folded upon itself, making again an oblong pad, having eight layers.



Folding it once more upon itself, the pad is then composed of sixteen layers and measures 9 inches square. To keep the pad in shape and the layers from becoming separated the edges are stitched together with ordinary sewing cotton. The small pad is made in a precisely similar manner, except that a piece of gauze 18 inches square is used.

The advantages of these pads over sponges are very great. Flat sponges are not only expensive, but it requires great care and trouble to render them aseptic.

Again, they can be used only a few times, as the chemical processes through which they must pass in cleaning after an operation render them rotten and unfit for use. Indeed, it is a serious question—one that for myself I have long since decided in the negative—if a sponge should ever be used a second time in abdominal work. Certainly, the best results are obtained in this branch of surgery by those operators who are extravagant in the use of their materials and who never use ligatures or sponges left from a previous operation. Finally, sponges necessarily swell when brought in contact with fluids, and consequently they do not remain well in the position in which they are placed. On the other hand, gauze pads are inexpensive, the material costing only 2¾ cents a yard; they are readily made, and easily rendered aseptic by simply placing them in a steam sterilizer for forty-five minutes prior to using them. Again, they remain well in place, as they retain their shape perfectly and are much easier to pack about the seat of operation than are sponges.

A CASE OF LONGITUDINAL FRACTURE OF THE PATELLA.

BY A. H. FRASER, M.D,
LICENTIATE OF THE ROYAL COLLEGE OF SURGEONS, EDINBURGH,
OF HARPER, KANSAS.

THE literature concerning fractures of the patella other than transverse is so meager that a case of longitudinal fracture becomes one of interest and importance. Dupuytren only met with four cases, and Hamilton, in his book on *Fractures*, gives 127 cases wherein the knee-cap was fractured, 106 being transverse, some oblique, stellated, and comminuted, but longitudinal fractures are not mentioned.

On the night of September 19th last, I was asked to see a case of gunshot wound of the left knee, with my friend, Dr. W. G. Muir, of Harper. The patient was a young man, twenty-four years of age; there was an external wound one-eighth of an inch to the outer side of the middle line of patella; the bone was split into two almost equal parts; the bullet, having taken a downward and slightly outward direction, was found just below the outer head of the femur, lying transversely and at right angles to the shaft of that bone. The injury took place at very close quarters, the patient's right wrist being burned by the powder while endeavoring to turn aside his assailant's pistol. It seems almost incredible that a man could run after receiving an injury such as that described, but the fact remains that he not only did not fall, but also ran a distance of fifty yards at a good pace; it may be that "fear lent him wings." A second shot was fired at him as he ran, and grazed the lower edge of the right buttock, but only had the effect of accelerating his speed. The patient being fully placed under the influence of chloroform, the original wound was somewhat enlarged and an attempt was made to seize the bullet with a pair of forceps, but it was found that the detached outer fragment was too much in the way, and the bullet could be felt just above the outer tuberosity of the tibia; an incision was made over that point, and a 38-caliber revolver bullet removed. The limb was kept extended; the edges of the fractured patella were brought firmly into apposition, and retained by means of adhesive plaster; after being washed out with warm carbolic lotion, a drainage-tube was inserted into the lower wound, which was dressed with iodoform and dry cotton, the whole being enveloped in a figure-of-eight bandage. Uninterrupted recovery took place; the upper wound healed by first intention; there was no rise of temperature; there was extraordinary freedom from pain.

The joint was daily syringed out with warmed carbolic lotion; the drainage-tube was removed on the tenth day—there being less than two teaspoonfuls of pus in the whole course of the case. Three weeks after the injury the patient was up and going around on crutches. I had an opportunity of seeing the case three months afterward, when perfect bony union had taken place; the man could bend one knee as well as the other, and walked without any limp and quite unaided by an artificial support of any kind. In all probability, had a man received an injury to the knee-joint such as is here recorded involving the knee-joint and destroying the bursæ, twenty years ago, it would have been considered a fit case for amputation; whereas now, with antiseptic dressings and thorough cleanliness, the whole thing is healed up within three weeks.

MEDICAL PROGRESS.

Unusual Phenomena of Epilepsy.—In an interesting address, WILKS (*British Medical Journal*, No. 1618, p. 2) reports a number of unusual phenomena observed in connection with epilepsy, the significance of which might readily escape the unobservant. He takes the view that the association of loss of consciousness, convulsions, and coma is not an essential feature of the disease. In some cases, there is only a strange feeling in the limbs or a sudden pain in some part of the body; in others, there is an aberration of the senses or a perturbation of an important organ; sometimes there is only a strange mental disturbance. Sometimes, the aura constitutes the main symptom of the attack; suspicion should be aroused if a patient complains principally of a sore tongue. There may be aberration or confusion of mind, the patient committing acts of which he subsequently has no recollection. The special senses or motility may be transitorily impaired or lost. In some cases, coma or sopor may be the only discoverable manifestation. Sometimes it would appear as if the attack were long drawn out—that is, instead of being shock-like and intense, it is protracted in duration and correspondingly mild in intensity. Wilks is averse to admitting any relationship between epilepsy and migraine. In his experience, the one does not replace the other; nor are both common in the same family. In the one, the onset is sudden, with convulsions, dilated pupil, congestion, and often, heat of body; in the other the onset is gradual, with contracted pupil, cold skin, and sickness. According to the observations of Wilks the epileptic does not suffer from headache.

Hysterical Mutism with Agraphia.—COURMONT (*Revue de Médecine*, 1891, No. 10, p. 895) has recorded the case of a man, forty years old, who, at twenty-two, after excitement, lost consciousness for thirty hours, and for twenty-four hours subsequently could not speak, but laughed constantly. Recovery took place in the course

of several days. On arising one morning, when thirty-two years old, the man found that he could move his left arm and leg only with difficulty. The condition improved in the course of a few days, but subsequently some degree of weakness of the left side was from time to time observed. Six months before coming under observation, there had been temporary loss of speech. Four months later, the occurrence was repeated, the face and tongue then deviating to the left. The condition disappeared in the course of a day. A month before the man presented himself, he again lost the faculty of speech, though he retained the ability to write. At the end of two weeks, speech returned for two days; then both faculty of speech and ability to write were lost. By gesture the patient indicated the existence of pain in the head, especially at the upper part of the left temporal region. He comprehended written and spoken language. There were thus no word-deafness and no word-blindness. The patient could neither transcribe nor write by dictation. There was no palsy. There was slight anesthesia upon the left side. The right field of vision was normal; the left was diminished about one-half. On the night after coming under observation, the condition spontaneously disappeared, and on the following day the man could talk volubly.

Perforative Aortitis.—OLIVER (*Lancet*, No. 3558, p. 1033) has recorded the case of a man, aged thirty-six years, who thirteen years previously had an aggravated attack of rheumatic fever. Murmurs indicative of the existence of aortic obstruction and incompetency, of mitral incompetency, and of pericarditis were heard and the heart was hypertrophied. Some time later the patient rather suddenly died. At the autopsy, the pericardium was found occupied by a clot entirely surrounding the heart. The heart itself was dilated and hypertrophied. The mitral orifice was dilated, the valves normal. The aortic valves were incompetent. The aorta, just beyond its origin, presented a pouch-like dilatation. Over a small area between the mouths of the coronary arteries, extending upward for about an inch and a half, the lining membrane of the aorta was red, softened, and ulcerated, and in two places gangrenous. From the center of this area a small pouch bulged outward. The walls of the pouch were thin and soft, and perforated at its base by an opening as large as the head of a pin. An atheromatous plate lay close to the orifice of the left coronary artery. Microscopic examination confirmed the macroscopic evidences of the existence of an ulcerative aortitis, and disclosed in addition the presence at the focus of inflammation of considerable numbers of bacilli resembling those of anthrax. There was no history or knowledge of infection.

A Needle in the Trachea.—At a meeting of the Laryngological Society of Berlin, SCHORLER (*Berliner klin. Wochenschrift*, 1891, No. 44, p. 1079) presented a tailor who, while at work, had drawn into the trachea a threaded needle that he was holding in his mouth. The protruding threads were secured by an additional thread, and attempts were made to withdraw the foreign body, but without success. On examination with the mirror, the needle was found impacted in the trachea at its bifurcation, one extremity being deeply imbedded in the walls of the trachea, and the other being caught below a ring of cartilage on the opposite side. As the patient began to display signs of fatigue, and as the symptoms were not threatening, further manipulation was postponed to the following day. Repeated attempts at removal failing, a laryngeal sound with a hook-like extremity was introduced, for the purpose of dislodging the needle. A little manipulation released the foreign body, which was then readily withdrawn. In the course of three or four days the patient was restored to his usual condition.

Treatment of Diphtheria.—SMITH (*The Practitioner*, No. 282, p. 430) has successfully employed carbolic acid by continuous inhalation in seventeen cases of diphtheria. He ascribes the good results largely to the method of application. The patient is placed in bed, lightly clad and made to maintain the recumbent posture. Over him is placed a tent, made of a sheet, closed on all sides except in front. Cloths, about a foot square, soaked with a mixture of carbolic acid, one part, oil of eucalyptus, one part, and turpentine, eight parts (or less, according to indications), are hung about the patient, while the surrounding air is constantly kept impregnated with the vapor of steam. The cloths are to be re-soaked as they become dry. The patient should breathe through the mouth. If necessary, the nostrils may be loosely plugged with cotton-wool. The inhalations do not counter-indicate the employment of other therapeutic measures. Should there be depression, alcohol, digitalis, belladonna, or ammonia may judiciously be administered.

Distinctions Between the Bacillus of Typhoid Fever and the Bacillus Coli Communis.—At a meeting of the Société de Biologie, DUBIEF (*La Médecine Moderne*, No. 43, 1891, p. 745) reported that in making comparative experiments with the bacillus of typhoid fever and the bacillus coli communis, he found that both organisms caused the fermentation of glucose in about equal degree, the colon-bacillus, however, giving rise to the formation of a larger percentage of lactic acid. In consequence of this difference, the typhoid-bacillus but slowly causes the coagulation of milk, while the colon-bacillus produces the same result more speedily.

Before the Académie de Médecine, ROUX and RONDET (*La Médecine Moderne*, 1891, No. 43, p. 741) maintained the identity of the bacillus coli communis and the bacillus of typhoid fever. The apparent differences that exist are considered as dependent upon the varying conditions to which the organism may be exposed.

Pyoktanin in Ophthalmic Practice.—As a result of the employment of pyoktanin for a period of three months in the ophthalmic service of Bacchi, RESCOUSSIE (*Annales de la Policlin. de Paris*, 1891, No. 12, p. 549) concludes that the agent is an excellent antiseptic in ocular surgery—to be preferred to all others. It exercises a favorable influence upon simple conjunctivitis, and especially upon granular conjunctivitis. It is of doubtful efficacy in case of rebellious ulceration of the cornea, and is almost useless in case of purulent ophthalmia.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

PHILADELPHIA.

SATURDAY, FEBRUARY 20, 1892.

"INFECTION" OR "CONTAGION?"—A QUESTION OF DEFINITION.

ASK anyone that has not previously made a special study of the matter, what is understood, or what should be understood, as the distinctive difference of definition between the two words, "infection" and "contagion," and it will soon be discovered that he has either no clear opinion, or an erroneous opinion about it. Then, go to the dictionaries, and it will be found that no distinction exists, or that an attempted distinction, either in logic or in fact, does not hold.[1] This is unfortunate and confusing. If the two words are identical in meaning, one is unnecessary, and should fall into disuse. But everybody has a

[1] To illustrate the unfortunate contradictions and indefiniteness of lexicographers and writers we append several excerpts:

INFECTION: The act or process of infecting, formerly applied to communication of disease without personal contact; now often used as synonymous with contagion, but is usually understood to refer to things rather than to persons. A disease is said to be infectious when it can be communicated to another person. CONTAGION: The process by which disease is transmitted. If by direct contact, it is called personal contagion. If indirect, it is often called infection. CONTAGIOUS: Capable of communication from one person to another, either by actual contact or through the air.—BILLINGS.

CONTAGION: The communication of disease from one individual to another by means of direct or mediate contact, or, as used by some writers (in the sense of infection), by effluvia, etc. 2. The material cause or virus of a contagious disease. INFECTION: The act or process by which disease is set up in an organism by the implantation of morbific germs from without, or in a part of the organism by the conveyance of such germs from another part. Infection differs from contagion in the fact that the germs are not necessarily transferred from another organism, and, as used by some writers, in the further fact that when they are, contact of the two organisms is not requisite.—FOSTER.

INFECTION is often used in a definite and limited sense, of the transmission of affections without direct contact of individuals or immediate application or introduction of the morbific agent, in contradistinction to contagion, which then implies transmission by direct contact.—WEBSTER.

INFECTION: Communication of some quality, property, or state, whether good or bad, by contact, diffusive, or emanative influence, example, etc. The communication of disease or of disease-germs, whether by contact with a diseased person, or with morbid or noxious matter, contaminated clothing, etc., or by poisonous exhalations from any source.—THE CENTURY.

INFECTIOUS: Communicable by infection; easily diffused or spread from person to person or from place to place, as a disease, a moral influence, or a mental condition; specifically applied to diseases which are capable of being communicated from one to another, or which pervade certain places, attacking persons there, independently of any contact with those already sick. Infectious diseases include contagious and miasmatic diseases.—THE CENTURY.

A distinction between contagion and infection is sometimes adopted, the former being limited to the transmission of a disease by actual contact of the diseased part with a healthy absorbent or abraded surface, and the latter to transmission through the atmosphere by floating germs or miasmata. There are, however, cases of transmission which do not fall under either of these divisions, and there are some which fall under both. In common use no precise discrimination of the two words is attempted.—THE CENTURY.

From an early period it has been observed that certain diseases are contagious or "catching," by direct contact with the sick person, or by means of clothing or buildings, which transmit the *materies morbi*. When actual contact took place the disease was called "contagious"; when it was transmissible by the air, it was given the wider name of "infectious."—FAGGE'S *Practice of Medicine*.

Dr. T. Mitchell Prudden defined the word "contagion" as an "invasion and reproduction within the body of pathogenic organisms." It was not necessarily an invasion by bacteria, because other organisms may be elements of contagion, as, for instance, in malaria. It was encouraging to note that the word "contagious" no longer refers to infinite possibilities in the unknown, for the contagium in an infectious disease is the particular pathogenic microörganism itself, whose advent in the body ushers in those reactions of the body cells that we call the disease; and an infectious disease is contagious when the contagium, under the ordinary conditions of life, can be freed from the body of a diseased person and be conveyed to the body of another, in such a condition as to be able to reproduce the disease in this second individual. Hence, the old distinction between contagion and infection has become impracticable and valueless, as it is now known that the communicability of an infectious disease is largely dependent upon the physical properties of the contagia, which determine the manner in which they are spread from body to body or from place to place. The common conception of a contagious disease is one which taints the atmosphere surrounding the patient, but this is not true of any of the ordinary diseases except the exanthemata. Thus, typhoid fever, diphtheria, and tuberculosis may be highly contagious, depending upon the care or lack of care taken in disposing of the exudates and discharges. —*New York Academy of Medicine*, January 21, 1892. (See THE MEDICAL NEWS, February 6, 1892, p. 164.)

more or less vague idea that some difference of meaning does exist, at least in the minds of the learned, but that the ordinary mortal has not succeeded in grasping it. The simple fact, however, appears to be that certain writers have endeavored to make distinctions of different kinds, but that such distinctions have not been univesrally accepted. Hence the general mystification.

This unfortunate haziness of mind in part arises from the patent fact that Science is not clear as to the means of communication of the diseases vaguely classed as specific, infectious, contagious, or zymotic. The difficulty of definition of terms is, in part, due to our incertitude as to facts; we do not know whether the specific viruses of certain diseases are transmissible only by direct contact, or also by certain intermediate agents, and moreover, by just what agents. There is also doubt whether certain diseases are due to a chemic or to a living agent or cause; and, finally, there is or may be some doubt as to whether or not a pathologic condition is purely idiopathic or non-transferable.

It is probable that this lack of certainty as to specificity or transmissibility of disease will long and possibly forever persist. In the meantime it is extremely important that clearness be provisionally attained by attaching such precise definition to terms as will make mutual understanding quickly possible, and that yet shall not bias the mind or make future changes and reversals of meaning necessary. The scientific world is now in a tangle of absurd misunderstanding as to the meanings of the terms ptomaïne, leucomaïne, toxalbumin, toxin, etc., all because the early nomenclature falsely presupposed certain questions of etiology, etc., as scientifically settled. Our naming of new facts should be as loose and large—as colorless and pliant as possible. The nomenclature should not enslave the facts or be inconsistent with new facts that may in time upset old theories. Had this rule been followed, it would not be true, as it now is, that a ptomaïne may be a leucomaïne, and *vice versa;* that a toxalbumin may not be an albumin at all, etc. (See editorial, THE MEDICAL NEWS, July 18, 1891.)

It may be said that the best way to avoid the trouble about the words *infection* and *contagion* is to drop one of them. The rub is that words refuse to die or to be born and live according to any dictum. The best-formed and most-needed of words will come into the world still-born, and all the labors of the philologic doctors with artificial respiration cannot bring about natural respiration. Conversely, the most execrable of philologic hybrids and teratologic absurdities will live and grow despite all attempts at asphyxiation and overlaying. The best we can hope to do in the latter case is to educate the youngster. As regards the two words under discussion, it appears like a case of rival twins competing for the right of primogeniture.

Etymologically the word *contagion* implies contact, touching, physical taking by one person from another of the *materies morbi.* But, of course, even that act may have a multitude of methods and degrees, and when a closer scrutiny is attempted there is found to be no essential difference between receiving the pathogenic matter from another by touching him, or the things that he has touched, and the transfer of the matter by a fly, by water, or by wind. The innumerable methods whereby the pathogenic material may be carried make it impossible to devise a nomenclature that shall express each variety of transfer. And yet it is precisely this idea of the method of transfer that has introduced the confusion complained of, and that makes it desirable to delimit the significations of the two words.

So far as we have now reached, it becomes most desirable to determine whether pathogenic material may be transported by the air or not. In the prophylaxis of disease this is an extremely important point. If, *e.g.*, pathogenic material may be transmitted through the air it is of the greatest importance to know the fact; but if not, then preventive measures are more easily instituted and made effective.

The word infection is, etymologically, not rigidly physical in its significance, and, in actual usage as well as in figurative meaning, it has the significance of more subtle and mysterious processes than those of the physical contact implied by the word contagious. May we not act upon this hint and conveniently limit the word *contagion* to those germs or that material not transportable by the atmosphere, and *infection* to that material that lives and is conveyed by aërial currents? Such a practice would permit both words to be used, but would give to each a distinct province and application, and thus avoid the present misunderstanding and confusion. Typhoid fever (unless the germs are later to be proved conveyable by air-currents) would thus

be a contagious, but not an infectious, disease; ague would be infectious, but not contagious; while tuberculosis would be both contagious and infectious, etc.

The objection to this suggestion that arises is that we are left without a generic term applicable to all diseases whether contagious or infectious. But, zymotic is such a word, with the widest significance and correctness of application.

Without some such limitation and definition as the foregoing we shall have to drift on, with the three words contagious, infectious, and zymotic, indiscriminately used, erroneously supposed to have differences of meaning, and giving rise to constant misunderstanding and mystification.

TWO METHODS.

To a physician of Philadelphia, widely known and greatly honored, an enterprising firm of dealers in wine lately sent a most lavish and costly case of "samples" of their "medicinal" beverages. The enterprising firm was thanked, and politely informed that the present had been re-presented to ——— Hospital.

Another physician writes an effusive and laudatory letter in praise of the wine, as regards its prophylactic and curative properties in disease, and this letter will doubtless be poked under the nose of every one of us for years to come.

In certifying to the superior excellences of one special preparation, it goes without saying that as a scientific man the physician has made impartial scientific analysis and tests of all competing preparations of the kind, and chemically, physiologically, and therapeutically is disinterestedly certain that the one he pronounces the best is really so. If he has not done so his certificate is a farce and he has unjustly discriminated against other preparations, possibly equally as good, the makers of which trust to the qualities of the preparations rather than to sly advertising dodges. But whatever the fact, either he has been foolish enough to give a valuable thing for nothing, or he has had value received for the puff.

SELECTION.

OUT-PATIENT REFORM.

The Great Northern Central Hospital, on establishing its new buildings in the center of the northern districts of London, found it necessary to rid its out-patient department of some of the evils that are usually comprised under the name of "hospital abuse." These evils, briefly stated, consist in the overcrowding of the departments, and in the presence among the patients of (1) persons whose position and weekly earnings render them well able to pay for treatment at their own homes; (2) persons who are suffering from chronic and trivial ailments; and (3) persons who, being members of clubs or of provident dispensaries, are already provided with means of medical aid in case of sickness. To eliminate these component parts of the crowd and to relegate them to their respective positions has been the aim of many schemes of out-patient reform in London as well as in some of the large towns in the United Kingdom. The experience thus gained has abundantly illustrated the truth of the saying that men cannot be made moral by Act of Parliament. No system has yet been devised that, depending for its success on the good feeling or the moral sense of the masses, has as yet fully achieved its object. The Great Northern Hospital system has been so framed as to be, for the most part, independent of the moral obliquity of individuals. It consists essentially of a system of inquiry into the circumstances of all applicants for relief and the refusal of all that exceed a definite wage limit laid down by the hospital authorities. All cases are further made to pass through the hands of a qualified casualty officer, who is required to be a resident in the neighborhood of the hospital, and by him the trivial cases are separated from the cases of real disease or injury. No case is refused first aid, but all cases refused further treatment under the wage limit are offered a form of certificate that, if they can get signed by their own physician, entitles them at their next visit to be registered as regular out-patients. The working of the scheme is controlled by a mixed medical and lay subcommittee that is responsible for all of the acts of the inquiry and casualty officers. In any case of doubt as to the truth of a patient's statements the subcommittee is empowered to institute inquiries at the patients' own homes. The objects of the Great Northern Hospital Committee have thus been threefold. While protecting the funds of the hospital from misapplication, it has also borne in mind the interests of the local practitioners, and has further rendered the labors of its own honorary medical officers less onerous and more effective by the system of preliminary medical inspection. The patients themselves receive treatment in accordance with their requirements, and although the scheme may be objectionable in the eyes of the few upon whom it operates, it would appear to be popular with those whom it protects. It is worthy of note that a form of voluntary pay system was for a long time in vogue at the Great Northern Hospital, and that it failed signally to check the ordinary forms of abuse. The practitioners in the neighborhood of the hospital rose up in arms against it, and at the instance of its own medical officers the committee withdrew it. Pay systems, as established at Guy's Hospital, the Queen's Hospital, Birmingham, and elsewhere, whether accompanied by inquiry, or whether put on the same footing as at the provident dispensaries, are, and must be, liable to abuse. Rigid and regulated inquiry would seem to be the only effective means of detecting such abuse, but unless universally adopted will only have the effect of driving unscrupulous persons from one institution to

another. Combined action, as attempted among certain of the Manchester medical charities, or by the agency of the Charity Organization Society, would probably prove the most economical method, but it is open to question whether the more effective results would not be obtained if every hospital protected its own interests as the Great Northern Hospital has done.—*Brit. Med. Journ.*

REVIEWS.

Physical Diagnosis. A Guide to Methods of Clinical Investigation. By G. A. Gibson, M.D., D.Sc., F.R.C.P. Ed., Lecturer on the Principles and Practice of Medicine in the Edinburgh Medical School, etc., and William Russell, M.D., F.R.C.P. Ed., Pathologist to the Royal Infirmary of Edinburgh, etc. With one hundred and one illustrations. 8vo, pp. 376. New York: D. Appleton & Co., 1891.

The importance of diagnosis in the practice of medicine is amply testified to by the large number of books on the subject, of which there are many that are good. The diagnosis of disease is a most interesting subject, calling into play, as it does, the highest intellectual activity in conjunction with the broadest knowledge, in the face of which conditions apparently complex become reduced to their elementary simplicity. Based upon definite principles and accumulated observation, it is an exact study, attainment of proficiency in which depends upon careful training and unlimited experience.

Diagnosis depends upon a correlation of the physical signs and the symptoms. Careless observation or false reasoning may each lead to wrong conclusions. To prevent such untoward consequences the student should be instructed in the best methods of conducting clinical investigation, and he should understand the significance and the mechanism of the results of such investigation. The book of Dr. Gibson and Dr. Russell is well calculated to meet the indications. It is clearly written, in an easy and agreeable style. Well-executed illustrations are introduced when necessary to elucidate or to amplify the text. It is only natural that here and there statements are made that will not find universal acceptance, that certain information is presented that it might be thought were well omitted, and that other facts are omitted that it may be thought it were better to have presented. It is stated that the precordia is normally slightly bulged as compared with the corresponding part of the thorax on the right side. We have found it far from usual that the precordia bulged appreciably, even in cases of hypertrophy of the heart. We are glad to see it stated, without qualification, that a mitral systolic murmur may occur "when there is no disease of the valve, but when the ventricle is dilated and enfeebled; then either the orifice is dilated, so that the cusps are to small too close it, or the muscle, owing to weak action, does not sufficiently contract the orifice to enable the valve to close it." To say that "in many cases of mitral stenosis, neither a diastolic nor a presystolic murmur is present, and yet the diagnosis may be made with practically absolute certainty" is to make rather a positive assertion the acceptance of which will depend upon post-mortem confirmation. Less than five pages are devoted to a consideration of the blood. The differential characteristics of the blood in anemia, chlorosis, pernicious anemia, leukemia, and pseudo-leukemia are not given. Among the microparasites of the blood the malarial organism is not mentioned. The chapter devoted to the urinary system is good and full, but no reference is made to the reaction of the urine in case of enteric fever to sulphanilic acid and sodium nitrite.

On the whole, the book can be safely entrusted to the hands of the student with the assurance that it will prove of real service.

Pulmonary Tuberculosis, Etiological and Therapeutic. Based on an Experimental Investigation. By R. W. Philip, M.A., M.D., F.R.S.E. 8vo, pp. 55. Edinburgh and London: Young J. Pentland, 1891.

The observations upon which this essay is based were begun in 1885. Premising his investigations by accepting the etiologic agency of the bacillus tuberculosis, Philip found that subcutaneous injections of an alcoholic extract of the pure sputum of unequivocal cases of pulmonary tuberculosis into cold-blooded and warm-blooded animals were invariably followed by symptoms of depression of the voluntary motor system, anorexia, and wasting, the action of the heart being slowed, with relative prolongation of the diastole. By the administration of atropine the effects of the injections were completely neutralized.

For therapeutic purposes pulmonary tuberculosis is divided into three stages: 1, a catarrhal or pretuberculous stage; 2, the stage of invasion, and 3, the stage of elaboration and absorption. In the first stage, the treatment must be prophylactic; especially is pulmonary exercise to be encouraged. In the second stage the treatment must be tonic and constructive; it is not necessary to attempt the destruction of the tubercle-bacillus; it suffices to render the soil unfavorable for its development. For this purpose "the group of bodies represented by eucalyptol, turpentine, terebene, copaiba (and perhaps creasote)," has proved useful. For two or three years Philip has advantageously employed pure oil of eucalyptus globulus, from ten to thirty minims, three or four times a day, conjoined with intra-tracheal injections of from a twenty to thirty per cent. solution of eucalyptus oil in olive oil or other bland menstruum. In the third stage of the disease, belladonna, or its alkaloid atropine, pushed to its physiologic effects, is indicated and has yielded satisfactory results.

Prescriber's Pharmacopeia. A Synopsis of the More Recent Remedies, Official and Unofficial, with a Therapeutic Index and a Résumé of the B. P. Additions, 1890. By a Member of the Pharmaceutical Society of Great Britain. Second Edition (revised reprint). Pp. 429. Bombay: Kemp & Co., Limited, 1891.

This booklet is a creditable compilation of the medicinal agents in more common and universal employ. It is based principally upon the British Pharmacopeia, though it contains not only preparations to be found in the British Pharmacopeia but also many recognized by the Indian, the German, and the United States Pharma-

copeias, as well as articles that have not received official recognition. The names of medicaments are arranged alphabetically. The qualities and properties, as well as the therapeutic indications of the representative of a class or of individual members of a class are presented, together with the chemical symbols or formulæ, the dosage, and in suitable cases with the antidotes and the incompatibles. An appendix contains the recent additions to the British Pharmacopeia and a consideration of the subjects of hypodermatic medication, pills, and urinalysis; it also contains other tests, a therapeutic index and a general index.

We are disposed to adhere to the standard works on materia medica and therapeutics, but we must admit that books like this Pharmacopeia possess a certain value in bridging over a period until new editions of standard works to conform to pharmacologic and pharmaceutic advance can be prepared. The completeness of the book and the evidence of carefulness it presents are praiseworthy.

TABLES FOR DOCTOR AND DRUGGIST. (Comprising: I. Table of Solubilities. II. Table of Reactions and Incompatibles. III. Table of Doses and Uses of Medicines. IV. Table of Specific Gravities. V. Table of Poisons and their Antidotes.) Compiled by ELI H. LONG, M.D., Professor of Materia Medica, Buffalo College of Pharmacy; Adjunct Professor of Materia Medica, Medical Department, University of Buffalo. Detroit: George S. Davis, 1891.

THIS is one of the most useful reference books which has come into our hands. The object of the compilation, which, as stated in the preface, is "to bring into convenient form for ready reference information that is wanted daily by the physician and pharmacist," has been admirably carried out. The Table of Reactions and Incompatibles constitutes the distinctive feature of the work. "It is not intended to be a technical guide for the chemist, but is arranged rather with a view to the practical needs of the practitioner." The Table of Doses and Uses is quite complete, and, so far as appears upon casual perusal, correct. The Table of Poisons and their Antidotes is also worthy of commendation; it is much fuller than the usual run of such tables. We regret to note, however, a number of serious omissions in the list of antidotes. Atropine and magnesium sulphate are both omitted from the list of antidotes of carbolic acid; amyl nitrite is not found in the memorandum of treatment of carbolic acid poisoning. In the treatment of strychnine poisoning, the importance of quiet and of the evacuation of the bladder has been forgotten. Nitrite of amyl might also well have been mentioned here.

MANUAL OF PHYSICAL DIAGNOSIS FOR THE USE OF STUDENTS AND PHYSICIANS. By JAMES TYSON, M.D., Professor of Clinical Medicine in the University of Pennsylvania, and Physician to the University Hospital, etc. 8vo., pp. 136. Philadelphia: P. Blakiston, Son & Co., 1891.

DR. TYSON has disarmed criticism as to the necessity for a new work on physical diagnosis by giving expression in his preface to the hope that his book may facilitate the teaching of the subject to his classes—and this object the book is admirably calculated to fulfil. The work contains a clear and concise description of the various phenomena elicited by physical exploration of the lungs and heart, in health and disease, based upon the results of a large and extended experience, during many years, in the employment of approved methods, and in the trial of proposed innovations. It is, however, to be regretted that a portion of the work was not devoted to a consideration of the information concerning diseases of the liver, spleen, kidneys, and other abdominal viscera to be gained by physical investigation. The results derived from physical exploration of the abdominal viscera are small as compared with those derived from physical exploration of the thoracic organs, partly because both subjects have not received the same degree of attention. The very obscurity of diseases of the abdomen should constitute a stimulus for the enlargement of our knowledge of the phenomena to be elicited by physical examination, and of the significance of those phenomena, so as to render more easy the recognition of those diseases.

DIAGNOSIS AND TREATMENT OF HEMORRHOIDS AND OTHER NON-MALIGNANT RECTAL DISEASES. By W. P. AGNEW, M.D. Second Edition. Pp. 148. San Francisco, California: R. R. Patterson, 1891.

IN addition to a consideration of the subject of hemorrhoids, to which this little work is largely devoted, the following subjects are briefly discussed *seriatim:* Rectal examinations, fistula in ano, ulcer, stricture, fissure and prolapse of the rectum, rectal pockets and papillæ, pruritus ani, divulsion of the sphincter ani, rectal polypi, proctitis, flushing the colon, reflex manifestations of rectal disease, condylomata, and neuralgia of the rectum. In an appendix, carbolic acid, cocaine, and the aspiration of hemorrhoids, are cursorily considered, and a few formulæ are added. The author is an advocate of the treatment of hemorrhoids by means of injections of carbolic acid. He employs a formula containing four drams of tannic acid carefully dissolved in an ounce of glycerin. To the solution two drams each of salicylic acid and sodium biborate are added. If there be any sediment the solution should be strained. Then to half an ounce of crystallized carbolic acid, liquefied by the addition of fifteen minims of distilled water, sufficient of the solution first prepared is added to make two ounces. From three to four minims are injected, in accordance with the size of the hemorrhoids.

TRANSACTIONS OF THE ASSOCIATION OF AMERICAN PHYSICIANS. Sixth Session, held at Washington, D. C., September 22, 23, 24, and 25, 1891. Volume VI. 8vo, pp. 319. Philadelphia: Printed for the Association, 1891.

AS the readers of THE NEWS have already been presented with a full report of the proceedings of the sixth session of the Association of American Physicians, and have had an opportunity of reading so many of the papers contained in the *Transactions*, extended review is uncalled for. We dare only refer to the beautiful tribute to Leidy made by the President in his opening address; to the original paper of Roosevelt on "The Frequency of the Localization of Phthisis Pulmon-

alis in the Upper Lobes;" to the advanced position taken by Delafield in suggesting a rational nomenclature for the "Diseases of the Kidney, Popularly Called Bright's Disease;" to the scholarly papers on "Arterial Disease," by Peabody and by Councilman; to the classical essay of Fitz on "Intestinal Perforation in Typhoid Fever." The *Transactions*, as a whole, reflects credit upon the Association.

Manual of Chemistry. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Text-book Specially Adapted for Students of Pharmacy and Medicine. By W. Simon, Ph.D., M.D., etc. Third Edition. Philadelphia: Lea Brothers & Co., 1891.

Among the many works on chemistry offered for the use of the medical student, there is probably none that outrivals Dr. Simon's work in practical arrangement and thoroughness. A special feature of the book, and one that deserves the greatest praise, is the presence therein of the beautiful colored plates representing fifty-six chemical reactions. To say that they are splendidly and artistically executed hardly does them justice. They must convey to the mind of the student lasting impressions of the color-changes that he has noted in his experiments in the laboratory, and the perusal of this work must recall them vividly to recognition. The many cuts are well selected, and the make-up of the book leaves nothing to be desired. As a student's manual this work is of the highest order.

The Physician as a Business Man; or, How to Obtain the Best Financial Results in the Practice of Medicine. By J. J. Taylor, M.D. Pp. 144. Philadelphia: The Medical World, 1891.

Dr. Taylor has admirably presented the commercial obligation of the community to the practitioner of medicine, and in so doing he has not failed to show the dereliction of the community. The subject is a well-worn one; it is none the less a live issue. The physician holds a unique position. As his relations to his clients are confidential, so does he depend upon the honor of those clients to grant him proper remuneration. To derive a proper inspiration for his work, the physician must be an optimist. He is a poor business man, if striving for gain at the expense of others constitutes good business. Dr. Taylor has indicated some of the ways in which the physician can protect himself against deception and imposition, he has laid down certain general business principles with which physicians should be familiar or which they can advantageously follow. The book can be profitably read by physicians and others.

The Rational Cure of Deafness and Discharge from the Ear. By Samuel Sexton, M.D., assisted by Alexander Duane, M.D. 8vo., pp. 89. New York: J. H. Vail & Co., 1891.

This brochure sets forth most satisfactorily the "modern treatment for the radical cure of deafness, otorrhea, noises in the head, vertigo, and distress in the ear." This treatment consists in excision of the membrana tympani and the two larger ossicula, stiffened and ankylosed as they are in chronic catarrh of the middle ear, and excision of the diseased remnants of the membrana and necrotic ossicles in chronic purulent otitis media. This operation is new in aural surgery, and brings about good results in cases heretofore considered irremediable. We hail the brochure that explains it as a beacon-light, piercing the fog that has so long hung about these two aural diseases. Dr. Sexton deserves great praise for his labors in this operation of excision of the membrana tympani, and the thanks of the aurist for the valuable hints contained in this little work.

A Manual of General Pathology and Morbid Anatomy. By H. N. Hall, Ph.G., M.D., Lecturer on Pathology, Post-Graduate Medical School, Chicago. 8vo, pp. 188. Chicago: Rand, McNally & Co., 1891.

This book is one of a class that cannot be too severely condemned. Not only is it entirely inadequate for the needs of the beginner, but it is characterized by defects and imperfections of statement that render it unsafe as a text-book or as a compend. Every page of the work bears evidence of gross carelessness, while errors of orthography occur without limit.

In both English and foreign languages there are good books on pathology and morbid anatomy of which the student can with confidence and advantage avail himself. It is no drawback that they are not abbreviated to the point of uselessness. The student of to-day at best does not read enough, and is thus untrained for independent thought.

The Supreme Passions of Man; or, The Origin, Causes, and Tendencies of the Passions of the Flesh. By Paul Paquin, M.D. 8vo, pp. 150. Battle Creek, Mich.: The Little Blue Book Co., 1891.

Dr. Paquin defines appetite as natural desire; passion as abnormal appetite; while vice is practically the satisfaction of passion. All depend upon stimuli, and each is developed respectively in accordance with the character and in proportion to the intensity of the stimulus. The most prolific as well as the most universal source of abnormal stimulation resides in immoderate living—over-indulgence in animal food, with deficient activity. The recognition of the cause gives the remedy. Dr. Paquin has zealously presented certain truths the general recognition of which, together with the application of the remedial measures to be deduced, could only inure to the common good.

Age of the Domestic Animals. A Complete Treatise on the Dentition of the Horse, Ox, Sheep, Hog, and Dog; and on Various Other Means of Determining the Age of Animals. By Rush Shippen Huidekoper, M.D. Illustrated with 200 engravings. Philadelphia: F. A. Davis, 1891.

This is a work of both scientific and practical value. Dr. Huidekoper has succeeded in making a book that is concise without neglecting important subjects. Depending principally on the teeth as an indication of the age of the animal, the author has tabulated the development and eruption of these structures in such a way as to make this information of much practical value to

veterinary surgeons. He has also given other indications of the ages of animals. The work is fully illustrated.

RECORD-BOOK FOR PHYSICIANS AND TRAINED NURSES. By L. O. VAN RIPER. Chicago.

THIS Record-book is made of about 100 pages, each of which contains columns for the registry of the temperature, pulse, respiration, the number of bowel movements, the frequency of micturition, the color and quantity of the urine, and the medicament, the stimulants, and the nourishment directed, as well as special instructions for every hour of the day.

CORRESPONDENCE.

THE TREATMENT OF INFLUENZA AMONG THE POOR.

To the Editor of THE MEDICAL NEWS,

SIR: Although numerous articles on the treatment of influenza or "la grippe" have appeared and continue to appear, I feel justified in presenting this communication, by reason of the successful treatment of sixty-five cases within a month among the poor, without the use of any of the new coal-tar products.

It is too much the custom among physicians to use indiscriminately every new remedy proposed.

My experience with phenacetin, antipyrin, and other of the recently introduced coal-tar products, leads me to believe that they are all more or less depressing, especially if administered to patients in whom the vitality is already lowered, such as are found among the poor. Having, therefore, abandoned the new drugs, I took refuge in quinine.

Between December 24, 1891, and January 24, 1892, I treated sixty-five patients suffering with "la grippe" and its complications. Most were cigarmakers. Twenty-eight, or nearly 42 per cent., were males; thirty-seven, or nearly 58 per cent., were females; thirteen, or nearly 20 per cent., had bronchitis; four, or nearly 8 per cent., had tonsillitis; eighteen, or nearly 28 per cent., presented severe cerebral and gastric disturbance. Nine cases were in children, all presenting catarrhal symptoms.

All were treated by the administration of quinine suspended in syrup of yerba santa. In cases marked by catarrhal phenomena, I gave the sulphate. When tonsillitis existed I gave the salicylate combined with eucalyptol. When cerebral manifestations were prominent, I gave the hydrochlorate with caffeine. In cases of gastric type I dissolved the quinine in liquor pepsini, and added compound tincture of cardamom. There were no deaths. All were able to resume their work in from four to fourteen days. As a rule, I restricted the diet to hot milk.

The most serious objection to using syrup of yerba santa is that most pharmacists keep on hand only the fluid extract, with which they extemporaneously mix syrup so that the resin is thrown down. The best method of preparing the syrup is to rub the fluid extract up with granulated sugar in a mortar, adding magnesia, then water, constantly stirring and filtering. Prepared in this way the syrup has all of its resinous matters finely suspended, while any bad taste is entirely covered.

Very truly yours,

JOS. F. CHMELLICEK, M.D.

309 EAST SEVENTY-SECOND STREET, NEW YORK.

DISTANT ACTION OF GLYCERIN IN SUPPOSITORIES, ETC.

To the Editor of THE MEDICAL NEWS,

SIR: My object in relating the following case is to try to throw some light upon the subject of the action of glycerin upon the bowels, the instance given seeming to show that the laxative effect of a glycerin suppository or enema is not confined to the parts with which it is brought in contact.

Mrs. ——, aged forty, a multipara, had carcinoma of the fundus of the uterus for more than one year, and during the last three months of her life all her alvine discharges were passed through the uterus and vagina. Neither cathartics nor enemata produced any fecal discharge from the rectum.

On one occasion, when she became uncomfortable from accumulation and hardening of the discharge, I introduced a large glycerin suppository into the rectum. Within half an hour it produced a copious and semi-fluid stool through the uterus and vagina, *but no discharge whatever from the rectum.*

I subsequently had the privilege of an autopsy, Dr. Theodore H. Seyfert assisting me. We found that the diseased fundus of the uterus had become adherent to, and ulcerated into the narrowed colon at its sigmoid flexure, almost severing the continuity, and detaching the mucous lining of the colon from that of the rectum, and *totally obstructing* the upper end of the latter by organized deposits.

As far as one instance can, this one appears to prove that the effect of the glycerin, though originating in the rectum, is not confined to it.

HORACE Y. EVANS.

PHILADELPHIA.

"A NEW SUTURE."

To the Editor of THE MEDICAL NEWS,

SIR: Referring to the "Description of a New Suture" on page 103 of THE MEDICAL NEWS for January 23, 1892, I beg to call your attention to the fact that in September, 1889, I read before the Philadelphia Obstetrical Society a paper on "An Easy Method of Repairing the Perineum" (published, with illustrations, in the *Annals of Gynecology*, October, 1889), in which I described a suture almost identical with that described in THE NEWS. I have used this mode of suturing since 1881, but did not claim it as *new*, believing it to be only a modification and improvement on the old-fashioned quill suture.

Yours truly,

JOHN C. DA COSTA, M.D.

NEWS ITEMS.

The Eleventh German Congress of Internal Medicine will be held at Leipzig from April 20th to 23d, under the presidency of Curschmann. Biermer, of Breslau, and Ehrlich, of Berlin, will discuss Grave Anemic Condi-

tions; Rosenstein, of Leyden, and Stadelmann, of Dorpat, will discuss Chronic Hepatitis. Other papers will be presented as follows: The Cause of Immunity and the Cure of Infectious Diseases, by Emmerich, of Munich; Uremia, by Peiper, of Greifswald; The Results of Removing Large Portions of the Spinal Cord (a report on observations made on dogs by Goltz and Ewald), by Goltz, of Strasburg; The Recognition of So-called Hepatic Colic, and of Pseudo-gallstones, by Fürbinger, of Berlin; Further Communications on Diabetes Mellitus Consecutive to Extirpation of the Pancreas, by Minkowski, of Strasburg; Treatment of Carcinoma, by Adamkiewicz, of Cracow; The Different Forms of Pneumonia, by Finkler, of Bonn; The Therapeutic Value of Blood-transfusion in the Human Subject, by Landois, of Greifswald; The Cure of Tuberculosis and the Biology of the Tubercle-bacillus, by Klebs, of Zurich; The Causes of Immunity and Cure, Especially in Pneumonia, by Klemperer, of Berlin, and Klemperer, of Strasburg; Immunity Against Infectious Diseases, by Buchner, of Munich. Gerhardt, Ebstein, and Von Jaksch have also promised communications.

An Army Medical Board will be in session in New York City, N. Y., during April, 1892, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before April 1, 1892, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing the Surgeon-General U. S. Army, Washington, D. C., DR. C. SUTHERLAND.

Rush Medical College.—A *concours* will be held at Rush Medical College, beginning Tuesday evening, March 1st, for the purpose of filling the positions of Lecturer on Anatomy and Lecturer on Materia Medica and Therapeutics in the spring faculty.

The spring course begins March 31st, directly after the close of the regular term, and continues two months, with a class of from 250 to 300 students.

It is the policy of the College, so far as practicable, to fill vacancies in the regular faculty from the corps of spring instructors. Nine of the present members of the regular faculty have been selected in this way.

The *concours* will consist of twenty-minute lectures by each of the applicants, before the faculty, students, and local profession, upon subjects pertaining to their respective branches, to be indicated by the Professor of Anatomy and the Professor of Materia Medica and Therapeutics a week before the contest.

An Orthopedic Department at the Philadelphia Hospital.—At a recent meeting of the Bureau of Charities a communication from Dr. H. Augustus Wilson was received proposing the establishment of an Orthopedic Department at the Philadelphia Hospital. The subject was referred to the Medical Board.

An International Gynecologic and Obstetric Congress will be held at Brussels in September of the present year. The following subjects will receive special discussion: Pelvic Suppuration, to be opened by Segond, of Paris; Extra-uterine Pregnancy, by Martin, of Berlin; Placenta Previa, by Hart, of Edinburgh.

Cremation.—A crematory is to be erected in the Berlin City Cemetery, which it is intended shall be superior to any in Europe.

ORIGINAL ARTICLES.

A STUDY OF THE BLOOD AFTER HEMORRHAGE, AND A COMPARATIVE STUDY OF ARTERIAL AND VENOUS BLOOD, WITH REFERENCE TO THE NUMBER OF CORPUSCLES AND THE AMOUNT OF HEMOGLOBIN.

BY GUY L. KIEFER, M.D.,
OF ANN ARBOR, MICH.

IT has been considered a fact that venous blood contains a greater number of corpuscles and a larger amount of hemoglobin than does arterial blood, but this statement has been contradicted recently by Cohnstein and Zuntz, who maintain that there is no such difference, and that the results obtained by previous investigators were due to the venous stasis caused by their experiments. The work of Cohnstein and Zuntz shows, as an average of eleven arterial determinations, 5,307,100 corpuscles per c.mm., and as an average of twelve venous estimations 5,191,600 corpuscles per c.mm. In order, if possible, to throw more light on this subject, I have made a number of experiments, the results of which will be seen in this paper.

Most of my experiments were limited to one mammal—the cat—in order that by confining the work to one kind of animal I might gain a certain degree of familiarity with the peculiarities of its blood, and thus obtain better results.

For the estimation of the percentage of hemoglobin in the blood, Gowers's hemoglobinometer was used, and for the determination of the number of corpuscles Malassez's hemocytometer, as made by Verick in 1883, with a 3 per cent. solution of sodium sulphate (sp. gr. 1025) as the diluting fluid. I made a number of estimates of normal human blood, with the following results: As a mean of five estimates on various men, 4,560,000 corpuscles and 90 per cent. of hemoglobin were obtained with the instruments used, and as a mean of four estimates of my own blood taken at different times, 4,800,000 corpuscles and 95 per cent. of hemoglobin. As a mean of twenty-one estimates on cats I obtained 6,646,000 corpuscles per c.mm. of blood, and 80 per cent. of hemoglobin. Blood for examination in the case of a cat was taken from the ear.

For the comparative study of arterial and venous blood two methods of procedure were employed.

1. An artery and its corresponding vein were laid bare for some distance, two ligatures applied simultaneously to each, and then the piece enclosed between the ligatures was removed, and the blood contained in it examined. Due care was taken to dry the outside of each vessel, so that only the particular kind of blood desired was obtained.

2. An artery and its corresponding vein were laid bare, and a little blood taken from each (without applying any ligatures) by means of a hypodermatic syringe. Care was taken to clean and dry the instrument thoroughly before each estimation.

By these methods the circulation was not interfered with. During all the experiments the cats (or other animals) were kept tied down, and anesthetized with ether. Inasmuch as I had but one hemocytometer and hemoglobinometer at my disposal, I could make but one determination at a time, but the other was made as soon as possible thereafter; and in order to counteract the difference that might be brought about by this circumstance, I examined the vein first in some experiments, and the artery in others.

Seven experiments were made, with the following results: In all of the experiments, except one, there was a slight difference in favor of the vein, and the average of all the experiments showed a difference of 60,000 corpuscles per c.mm., and less than 1 per cent. (0.33) of hemoglobin, in favor of the vein; but in determinations of this kind this slight variation is within the limits of error. My experiments would lead me to believe, therefore, that there is very little or no difference in the amount of hemoglobin and the number of corpuscles in the arterial and venous blood, and that the large differences usually reported are due to interference with the venous circulation, as claimed by Cohnstein and Zuntz. But in order to be convinced on this point, I made a number of experiments for the estimation of the venous blood before and after ligating the vein, *i. e.*, before and after interference with the circulation.

The methods of obtaining the blood were the same as those employed in the first set of experiments, viz., by taking out a piece of the vein, and by means of the hypodermatic syringe. In cases in which the latter method was employed the vein was laid bare, and a drop of blood taken by means of the syringe and examined. Then the vein was ligated, and a short time afterward a drop of blood was

taken on the peripheral side of the ligature and examined. In cases in which the former method was used the vein was laid bare, and two ligatures were applied simultaneously. After ligating the vein again, on the peripheral side of the section just isolated, the piece was removed, cleaned, and examined as before. After a short time another ligature was applied to the peripheral side of the one last made, and this piece was also taken out and examined. By these two methods I was enabled to get satisfactory samples of venous blood before and after venous stasis had been produced. In these experiments I ascertained simply the number of corpuscles in order to facilitate the work, and as the amount of hemoglobin is in proportion to the number of corpuscles, an estimation of it seemed unnecessary.

All of my experiments (eight in number) show a considerable increase in the number of corpuscles after ligating, the difference in one case being over a million. The average of all the experiments made shows an increase of 537,500 corpuscles per c.mm. after ligating, and we may conclude, therefore, that the large differences found by previous workers were due to this cause.

A study of the regeneration of the blood after hemorrhage involves a consideration of two other questions, viz.: 1. Are the amount of hemoglobin and the number of corpuscles diminished in proportion to the amount of blood lost, *e. g.*, after a hemorrhage of 100 c.cm. of blood will the diminution in the amount of hemoglobin and the number of corpuscles be twice as great as after a hemorrhage of fifty c.cm. of blood? 2. Are the amount of hemoglobin and the number of corpuscles always in proportion to each other after hemorrhage, *i. e.*, during the entire period of regeneration?

In all of my experiments the animals were bled from the carotid artery. An ordinary glass canula, of as large a caliber as possible, was used, and the blood allowed to flow quite rapidly. In some cases, when the hemorrhages were very severe, a quantity of normal saline solution was injected hypodermatically immediately after the blood had been drawn. None of my observations were made immediately after the hemorrhage. Twenty-four hours were allowed to pass in each case before making an estimation. The blood for examination was taken from the ear by clipping it very slightly. In each case there was a diminution in the amount of hemoglobin and the number of corpuscles twenty-four hours after the hemorrhage, and this diminution was found to be substantially in proportion to the amount of blood taken. For example, in the case of the slightest hemorrhage that was produced (2.1 per cent. of the body-weight), the amount of hemoglobin was reduced to 52.85 per cent. of the normal, and the number of corpuscles was reduced to 61.8 per cent. of the original number; while in the case of the largest hemorrhage (3.04 per cent. of the body-weight), the amount of hemoglobin was reduced to 46.6 per cent., and the number of corpuscles to 48.7 per cent. of the normal, and the same relation existed in each case. Whether or not the same result is obtained when the hemorrhages are less severe was not determined. From the results just given it would appear that in each case after hemorrhage the diminution in the amount of hemoglobin is greater than that in the number of corpuscles, but this is not necessarily the case. My first estimations after the hemorrhage showed in some animals an equal diminution in the amount of hemoglobin and the number of corpuscles, while in other cases the diminution in the amount of hemoglobin was the greater.

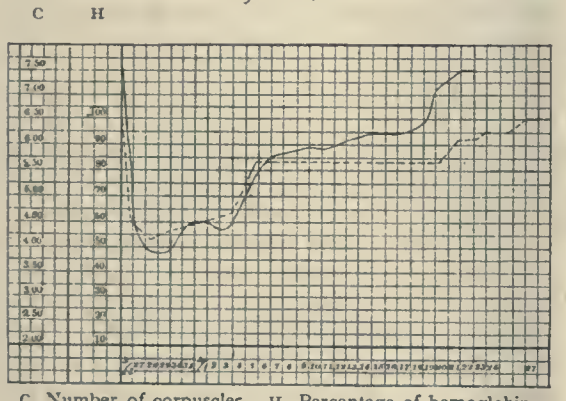
With reference to the second question, it will appear from the curves of regeneration that in each case it took a longer time for the amount of hemoglobin to return to normal than for the number of corpuscles. From this circumstance we may conclude that after hemorrhage the amount of hemoglobin is not always in proportion to the number of corpuscles, and probably for the reason that the new corpuscles are formed more quickly and in greater quantity, and consequently contain less hemoglobin, than the normal.

For the study of the time of regeneration of the blood daily estimations were made after the hemorrhage, and the data so obtained were used to construct curves of regeneration. In each case the animal was bled, as described, and was fed on milk and meat during the regeneration. The animals were studied one at a time, as far as possible, and were kept in a large cage, with plenty of air and light.

From the curves constructed from the experiments it appears that the diminution in the number of corpuscles, and in the amount of hemoglobin, continues for a number of days after the hemorrhage, reaching its minimum in from two to seven days, after which there is a steady rise to normal in the case of the corpuscles, but in the case of the hemoglobin the curve is somewhat different. During the period of fall and the first portion of the period of rise the hemoglobin and corpuscle curves are very similar; then for some time the hemoglobin lags behind the corpuscles until nearly the time when the corpuscles are restored to normal, when it takes a sudden rise and reaches normal somewhat later than the corpuscles. The specimen curve given in the accompanying figure illustrates very well the two peculiarities described. The entire time of regeneration was found to vary from twenty-one to thirty-four days. My experiments confirm the

results reached by former investigators. Otto found that the minimum diminution was reached in from one to five days, and that the time of regeneration varied from seven to twenty-five days. Hünerfauth (Heidelberg) found that the minimum was reached in from one to nine days, and the normal in from fourteen to twenty-two days. According to Buntzen the number of corpuscles is reduced after hemorrhage, and reaches its minimum in from one to eleven days, and the entire period of regeneration, according to this author, varies from

EXPERIMENT NO. 6. Cat: weight, 3628 grams. Hemorrhage, 90 c.cm.



C. Number of corpuscles. H. Percentage of hemoglobin.

Curve showing the regeneration of the red corpuscles and of the hemoglobin after hemorrhage. The experiment was made upon an unusually vigorous animal, so that the regeneration was more rapid than in most of the experiments. The full line gives the curve for the corpuscles, and the dotted line that for the hemoglobin. Observations were made at intervals of twenty-four hours from the 26th of March to the 27th of April.

nine to thirty-five days. There does not seem to be any explanation given for the continued diminution of the number of blood-elements during the first days after hemorrhage. Leaving aside mere variations in the amount of blood-plasma, two possible explanations have suggested themselves to me. The continued sinking in the number of corpuscles and in the amount of hemoglobin after hemorrhage may be due to the fact that the consumption of blood-corpuscles during this time is greater than the regeneration, owing to some acceleration in the body-metabolisms, or possibly there may be a scarcity of material for the manufacture of new corpuscles, so that after the first output of corpuscles from the hematopoietic organs, brought about by the anemia, the reserve supply is depleted to such an extent that for some days the production of new red corpuscles is smaller than it was immediately after the hemorrhage. This latter hypothesis is one that may be tested directly by examinations of the marrow; experiments of this kind may be made later in this laboratory.

PHYSIOLOGICAL LABORATORY, UNIVERSITY OF MICHIGAN.

HEMOPHILIA.

BY B. K. RACHFORD, M.D.,
CLINICIAN TO CHILDREN'S CLINIC, MEDICAL COLLEGE OF OHIO, CINCINNATI, OHIO.

I WISH to place on record some cases of hemophilia in a family of bleeders, that, so far as I can learn, are not connected with any of the bleeder families hitherto reported. They occurred in the family of Charles Denner, a German-American farmer living in Campbell County, Ky., six miles south of Newport.

Denner is fifty-six years old. He was born in Bavaria, but came to this country when quite a young man. He married in Campbell County, Ky., and twenty-nine years ago settled on the farm he now occupies. He has four brothers and one sister, and they are living in this country. If there was any hemophilia in their ancestors, they know nothing of it. They never heard of the disease until it developed in this family. The wife was born in Campbell County, Ky. She died ten years ago, of peritonitis, after six days of illness. Her father, who is now living, never heard of hemophilia, and is quite sure that none of his immediate ancestors had it.

In short, the most careful investigation into the family history makes it probable that the disease originated in this family; but the most careful inquiry fails to throw any light on the causal conditions. There is no history or evidence of tuberculosis or syphilis in the family. There was no blood-relationship between the husband and wife. The family has always lived on a farm, and has had plenty of food, fresh air, and exercise. The boys and girls alike have been accustomed to the hardest kind of farm labor, and all except the bleeders are types of health and strength.

There were nine children in the family, four of whom are now dead.

Lizzie Denner, the oldest child, is not a bleeder. She is married, and has three children, all boys, one of whom is a bleeder. (Case III.)

Charley Denner, the second child, bled to death when two years and three months old. (Case I.)

Henry Denner, the third child, died when fifteen months old, of "summer complaint."

Kate Denner, the fourth child, died when one year old, of "summer complaint."

Harry Denner, the fifth child, was not a bleeder. He died, when nineteen years old, of peritonitis, which came on without apparent cause.

Martin Denner, aged sixteen, is strong and well. He was never sick, and is not a bleeder.

George Denner, aged fourteen, is a bleeder. (See Case II.)

Sallie Denner, aged twelve, is well, and is not a bleeder.

Willie Denner, aged ten, is well, and is not a bleeder.

From this family history the diagnosis of hemophilia is plain. The parents were non-bleeders, and they came from non-bleeder ancestors, yet they produced a family of bleeders, and the disease has passed by heredity to their grandchildren. Here we have the strange phenomenon of children inheriting from their parents a disease that neither of these parents nor any of their ancestors ever had. In this field for speculation we may suppose that two or more harmless factors were so united in the marriage of Charles Denner and his wife as to produce in their descendants this strange disease, the pathology of which is quite as obscure as its etiology. During the past few months I have tried, but failed, to make arrangements for studying the blood of the various members of this family. What I especially wished to inquire into was the comparative number of blood plaques to be found in the bleeder and the non-bleeder, believing as I do that such an investigation may throw some light on the pathology of this disease.

Now let me give a brief history of the cases, calling special attention to the method by which the bleeding was stopped in Case II:

CASE I.—On June 1, 1866, Charley, the oldest son, two and a half years of age, came into the house bleeding from the upper surface of the tongue, about half an inch from the tip. The parents thought the child had bitten its tongue, although there was no wound to be seen, or any evidence of injury other than the bleeding. The bleeding continued, notwithstanding competent medical attendance, until five days later, when the child died from exhaustion.

CASE II.—In 1884, George, aged seven years, bled for five days from a very small scalp wound. With two physicians in attendance, the bleeding was only finally controlled by perchloride of iron and compresses.

On May 30, 1891, I found this same boy, now fourteen years of age, awaiting me in my office. He told me that he had been bleeding constantly for the past twenty-six hours. The bleeding-point was in the median line of the upper surface of the tongue, about one inch from the tip. There was no history of injury or evidence of a wound, other than the blood oozing from the bleeding-point.

I learned from the boy's father, who accompanied him, the family history as I have narrated it, and the history of this boy's previous attack of bleeding seven years before. I also learned that during the last few years he had several times suffered from painful swellings of the elbow-joints, with a dark-blue discoloration of the skin near the joint. This history, together with the fact that the boy had been treated with styptics of various kinds before coming to me, at once made the diagnosis clear, and the prognosis very doubtful. The details of treatment during the next few days are of no special interest. Ergot and tincture of iron were given internally and applied locally; perchloride of iron, tannic and gallic acids, and nitrate of silver and other styptics were applied. Collodion and other applications suggested by medical friends were also tried. But in spite of all treatment the boy continued to bleed until June 2d, the fifth day of the hemorrhage. By this time he was quite weak, and had a tired, anxious look; his lips were pale, his pulse 120, and at times intermittent.

The morning of June 2d I searched in vain the largest instrument house in Cincinnati, hoping to find some instrument suitable for compressing the bleeding-point. Returning home, I remembered that I had in my possession a large clamp, made for work in experimental physiology. It was found and used in the following way: A small piece of cotton was saturated with Monsell's solution, and placed on the bleeding point. Over this was laid a larger piece of dry cotton to act as a compress. This compress in position, the tongue was engaged between the two brass plates of the instrument, the upper plate holding the compress in position. The nuts were now screwed down so as to hold the tongue securely in the grasp of the instrument. The tongue, with the instrument applied, could occupy its normal position in the mouth. The compression was continued for two hours, and during this time the grasp of the instrument was several times slightly relaxed to allow better circulation in the tip of the tongue. In two hours the instrument was removed, and the bleeding did not recommence. The boy very quickly recovered from the effect of this hemorrhage, and has had no bleeding since. But early in July both elbow-joints again enlarged, and were very painful, and near the joint were large dark-blue spots, marking the site of interstitial hemorrhages. Since this time the boy has been disabled the greater portion of the time by these painful joint-swellings.

CASE III.—A male child, two years of age, is the youngest of three children, all boys; the other two are not bleeders. The mother of this child is Lizzie Denner, the oldest child of Charles. The father of the child does not come of a bleeder family. The child at present has painful joint-swellings, marked with blue spots, showing interstitial bleeding. This child has twice had very dangerous hemorrhage from slight scalp wounds.

In this case the disease was inherited, and passed through a female non-bleeder to her male child, thus illustrating the important influence of heredity and sex in perpetuating this interesting and mysterious disease.

A CONTRIBUTION TO THE STUDY OF ACCIDENTS FROM EQUESTRIANISM.

BY J. N. HALL, M.D.,
OF STERLING, COLORADO;
EX-PRESIDENT COLORADO STATE BOARD OF MEDICAL EXAMINERS.

I HAVE records of forty-four consecutive accidents happening to horseback riders during the past few years, and present herewith an analysis of them. I

recall quite a number of minor injuries, mostly slight bruises and sprains, of which I have made no note. A vast number of this nature must have occurred here not demanding serious consideration, those discussed being such only as really demanded treatment. The accidents have been very largely among the cowboys of this region, but five of the whole number occurring in females. The cases are tabulated according to the most serious injury when more than one affected the same individual. Although most of those injured received bruises and contusions, in addition to the affection for which they have been entered here, in no case were these of sufficiently serious nature to demand consideration under other headings. There have been no fatal cases among them, and the recoveries have been what we may term surgically perfect, excepting as noted later.

Thirty-nine of the forty-four were males (88.7 per cent.), of an average age of twenty-three years. Five were females (11.3 per cent.), of an average age of twenty years. The head was injured six times, or 13.6 per cent.; the trunk three times, or 6.8 per cent. The extremities were affected in thirty-five cases, the upper in fifteen, or 34.1 per cent., and the lower in twenty, or 45.4 per cent. Of these thirty-five injuries that we might term unilateral, twenty were upon the left side, or 57.1 per cent., and fifteen upon the right side, or 42.9 per cent. I have had a strong impression that the left side sustained a far greater proportion of these accidents than the right, but this seems doubtful, judging from the limited material at our disposal, if there be any foundation at all for such a belief.

The injuries to the different parts have been generally from totally different causes. Those to the head, six in number, were, excepting one, from being directly thrown so that the head struck the ground. In the exceptional case the boy was dragged nearly a mile on his back by the stirrup. Of injuries to the trunk, one was caused by being struck by the saddle-horn, and the other two apparently by the horse rolling over the rider.

With the upper extremities the injury has been from striking the ground (in one case a building), often, no doubt, in the effort to save the face from injury. In all but two cases, on the contrary, the affection of the lower limbs has been from the weight of the horse's body, as it fell upon the part injured. In these two cases, synovitis of the knee occurred, apparently from the shock of alighting.

Of the whole forty-four cases there were: of fractures alone, seventeen instances; of dislocations alone, three instances; of fractures and dislocations in combination (both of the elbow-joint), two instances. Thus 50 per cent. of all injuries were included under fractures and dislocations.

There was but one compound fracture, this being of the right leg into the knee-joint, caused by the horn of the saddle after the rider lay on the ground. The simple nature of 95.5 per cent. of all these fractures and dislocations is in refreshing contrast to the compound injuries of this class so common in railroad and machinery accidents. I have included one case of separation of the epiphysis among the fractures. To me, the most surprising showing of this portion of the table is the relative infrequency of dislocations. Two of the three were of the shoulder, and one of the left metatarsal bone.

There were no fractures of the shaft of the humerus. In two cases the internal condyle was separated and both bones of the forearm dislocated, in one instance backward, in one inward. In one case the left external condyle alone was broken. The clavicle was broken in three cases, the left one in each. There was one instance of green-stick fracture of the bones of the right forearm, from the rider being thrown against a building by a bucking horse. Two Colles's fractures of the right arm were noted.

One robust young man (aged twenty-six) received an impacted fracture of the neck of the left thigh-bone as his horse fell upon him. His youth should be noted, although, inasmuch as the horse weighed about 1000 pounds, it would not seem that age could influence the result very much. There was but one fracture of the shaft of the femur, occurring in a man about twenty-five years of age, from a fall directly over a rail as the rider crossed the track, a led horse having pulled the ridden one over on to the rider.

But one comminuted fracture was seen, this being the compound one already mentioned. Four distinct pieces of the tibia were made out in this case. Both bones of the leg were broken in two other instances, the tibia only in one, and the fibula only in three.

There were six cases of sprained ankle, three of the right, and three of the left. As the milder cases of this injury rarely come to the notice of the surgeon in a sparsely settled country, I believe, from the number of cases of which I have known or that I have seen without being called upon to treat, that this is as common as all the other injuries together, for the foot is very frequently caught under the horse when turning suddenly, or in falling on slippery ground.

Two of the cases of concussion of the brain, one of them being the boy mentioned as having been dragged nearly a mile by the stirrup, have not been entirely sound of mind since; the other of these two cases showed, in addition, considerable wasting of the muscles of the left side for a year after being hurt. It is probable that something more than a

simple concussion occurred in these cases, although, as in both instances I saw them first several days after the injury, I am unable to say just what it may have been.

The man with the impacted fracture of the hip naturally has a slight limp, as I informed him that he would have. The fracture of the internal condyle, with dislocation of the radius and ulna inward, left motion limited to about two-thirds of the natural amount. This case was not seen by any physician until the sixth day, the family, in some unaccountable way, supposing it to be a simple sprain.

In the fracture of the thigh there was a shortening of one-half inch. I believe most of this would have been avoided had not the patient been a cowboy. The muscles of his thigh, developed by a life in the saddle, contracted very firmly, and I found it impossible to overcome the tendency to shortening.

ORIGINAL ADDRESS.

THE OBJECTS, PLANS, AND NEEDS OF THE LABORATORY OF HYGIENE.

An Address delivered at the Opening of the Laboratory of Hygiene of the University of Pennsylvania, February 22, 1892.

BY JOHN S. BILLINGS, M.D.,
DIRECTOR OF THE INSTITUTE; SURGEON, U.S. ARMY.

FROM those who have preceded me you have heard of the origin of this Laboratory, and something of the wishes, hopes, and expectations of the public with regard to it, as indicated by the donor, and by representatives of the University and the State.

You see clearly that this magnificent gift imposes a heavy responsibility upon those who are charged with the duty of managing it, and of seeing that it is so used as to meet the many and various demands which may rightfully be made upon it; and, in attempting to explain to you briefly what the Laboratory now is, and why it is as it is, I come before you oppressed with a keen sense of this responsibility, which is not lessened, but rather increased, by the fact that I feel that I am speaking to friendly critics.

For this new building, with its equipment and resources, is but an implement—a piece of mechanism—which may be used to shape products of vast importance, not only to the world as it is, but to generations not yet conceived; or which, on the other hand, may be so used as to be of little more importance to humanity than the toy tool-chest or the doll's-house of a child.

What this use shall be depends upon the force and skill applied to it; upon the materials submitted to it; upon the ability of those who guide it to foresee the direction in which at each moment of time it is best to move it; upon the knowledge and patience of those who are working in it; and, when all these are at their best, the results must still depend upon the decrees of Divine Providence, upon circumstances which no man can fully foresee, and which, therefore, no man can, with certainty, control to the end desired.

The position of laboratories in their relations to education, to science, to technology, and to the executive departments of governments and the welfare of the public, has become a very notable one within the last fifty years. A laboratory—or, as it was called in old times, an "elaboratory"—is, as its name indicates, a place for labor, for work—and especially for skilled labor, in the making of delicate and difficult observations and experiments; for analysis, to determine composition and causes; for synthesis, to determine the results of new combinations; for solving old problems, and for stating new ones. It is not a museum, or a store-room, or a show place; nor does this kind of a laboratory offer much for sale, except opportunity.

Only an opportunity—just a few possibilities, offered to the man who desires knowledge, who wants to see, and touch, and try for himself. Yet this offer of such an opportunity is what distinguishes it from those institutions established for the benefit of individuals.

The ideal laboratory of the alchemist or philosopher of bygone days was a mysterious, dusky place, the operations in which were kept a profound secret, and which thus gained in repute what they could not have obtained by publicity and free criticism.

Laboratories planned and fitted for public use, offering to anyone who is able and willing to pay a moderate fee and to submit to a few simple regulations, not only opportunities for learning the details of the processes carried on therein, but also facilities and means for making special research that he could only obtain otherwise at great expense and loss of time; such laboratories, I say, are all of comparatively recent date.

It is not yet twenty years since the first separate institution of this kind was established for hygiene—and even now there are not more than a dozen such laboratories, specially built and fitted for their purpose, in existence throughout the world. Of these, the best known is probably that of the University of Munich, under the direction of Professor Pettenkofer, while the largest is that of Berlin.

This laboratory is the first structure of its kind erected in the United States, and it therefore opens a comparatively new field of work in this country. What is the nature of this field, and what are its boundaries?

The object of hygiene is to preserve and to improve health, and there are few matters affecting the physical, intellectual, emotional, and moral condition of man as an individual, or of men in communities that may not come within the scope of its investigations. The destruction or avoidance of causes of disease is but a part of its objects—it is at least equally concerned with the means of making a man better fitted to resist these causes. "That kind of health," says Montesquieu, "which can be preserved only by a careful and constant regulation of diet is but a tedious disease." Disease, like health, is a vague term, including widely different and often very complex conditions, processes, and results, which must be observed, classified, and described in such a way that different men, widely separated in space and time, may know that they are seeing the same things, and thus may have the benefit of each other's experience.

In its scientific aspects, then—those which relate to definite and precise knowledge—hygiene rests largely on physiology and pathology, the third leg of the tripod being formed by vital statistics; while, in its practical

aspects, it must rest on chemistry, physics, and the data of sociology and politics.

At any given time, therefore, its scope and practical value must depend largely upon the breadth and solidity of the foundations which these various branches of science can provide for it. The opinions of the medical faculty of Paris as to the causes of the "black death," and the advice which they gave as to the means for lessening the "great mortality," absurd and preposterous as they now appear to us, were yet fully in accord with the knowledge and opinions of the time.

At the beginning of this century physicians did not distinguish with any certainty between typhoid, typhus, and malarial fevers; or between consumption and various other chronic diseases of the lungs, and, until this was done, investigations into the causes of these affections were necessarily almost fruitless.

When, however, a clue is once given to the student of causes, he may be able, by detecting differences in these causes, to call the attention of the pathologist to differences in the results, and thus the bacteriologist, by proving specific differences in microörganisms, all of which produce fever, suppuration, etc., induces closer study of details of cases by physicians, and the recognition of new and more clearly defined groups of symptoms and results, or, in other words, of new diseases.

We live in an age of specialization. Progress in science as a whole depends upon special progress in each of its branches. Our present knowledge of physiology depends largely upon the perfection of electric methods. Pathology and pathologic bacteriology are now waiting for increase of knowledge in organic chemistry. The law of evolution applies to this as it does to modern industrial progress.

The physician deals with sick men, and his first question is, What is the matter with this person? That is, What group of symptoms does he present, and to what derangement of his mechanism are these due? The hygienist deals with two sets of problems—the first relating to men who are not sick, and how their health and vital resistance-power are to be not only preserved but improved and strengthened; the second relating to sick houses, feverish blocks or wards, infected localities—where the first questions to be solved are, What are the causes of this condition of things? how have they found entrance? are they still acting?

In the investigation of causes he must consider not only the immediate or exciting, but also the remote or predisposing; not only those which are preventable, but those which, with our present knowledge, are unpreventable; and thus it is that heredity, race, local meteorology, occupation, and many other circumstances must be studied by him, as well as the effects of food, clothing, habitation, poisons, and viruses.

Much of all this was known to a few wise men long ago, as is shown by the scheme of inquiry stated by Lord Bacon in his *Articles of Inquisition touching Life and Death*:

"3. Inquire touching the length and shortness of life in living creatures, with the due circumstances which make most for their long or short lives.

"4. But because the duration of bodies is two-fold; one, in identity, or the self-same substance; the other, by a renovation or reparation; whereof the former hath place only in bodies inanimate; the latter, in vegetables and living creatures; and is perfected by alimentation or nourishment; therefore, it will be fit to inquire of alimentation, and of the ways and progresses thereof; yet this, not exactly because it pertains properly to the titles of assimilation and alimentation, but, as the rest, in progress only.

"Inquire touching the length and shortness of life in men, according to the ages of the world, the several regions, climates, and places of their nativity and habitation; . . . according to their races and families, as if it were a thing hereditary; also, according to their complexions, constitutions, and habits of body; their statures; the manner and time of their growth; . . . according to their fare, diet, government of their life, exercises, and the like. . . . But because it will be hard to know the ways of death, unless you search out and discover the seat, or house, or rather den of death, it will be convenient to make inquisition of this thing; yet not of every kind of death, but of those deaths which are caused by want and indigence of nourishment, not by violence; for they are those deaths only which pertain to a decay of nature, and mere old age. . . . Inquire touching the point of death, and the porches of death leading thereunto from all parts; so as that death be caused by a decay of nature, and not by violence."

Most of this is wise and far-seeing, yet little came of it for two hundred years. By way of contrast, let us take a few of the rules which Lord Bacon fixed for his own use, in order to prolong life:

"1. Once in the week to take the water of Mithridate distilled, and some grains of niter and saffron, in the morning between sleeps.

"6. To take every morning the fume of lign-aloes, rosemary, and bays dried, which I use; but once in a week to add a little tobacco, without otherwise taking it in a pipe.

"10. In the third hour after the sun is risen, to take in air from some high and open place, with a ventilation of musk roses and fresh violets; and to stir the earth, with infusion of wine and mint.

"17. To use once during supper-time wine in which gold is quenched.

"28. To provide always an apt breakfast."

A curious mixture of good-sense and rubbish, these rules, which are well worth reading.

The scheme of inquiry as to causes of disease and preservation of health to-day includes most of Bacon's questions, and also many others of which he did not dream. Let us consider, briefly, some of those which belong to our laboratory work.

The recent advances in our knowledge as to the action of certain microörganisms in the production of disease in animals and man have been largely made by laboratory methods, and indicate clearly that the study of bacteria and microzoa, and of their development, products, and effects, must be an essential part of the work of a hygienic laboratory, which should provide the peculiar arrangements and apparatus which are required for this sort of work. In fact, several so-called hygienic laboratories are simply bacteriologic laboratories, the interest in this particular branch of investigation having, for the time being, overshadowed all others.

Our laboratory, however, must provide also the means

for chemical investigations of air, water, food, sewage, secretions and excretions, and the products of bacterial growth; for testing the effects of gases, alkaloids, and albumoses of various kinds upon the animal organism; for investigations in the domain of physics, pertaining to heating, ventilation, house-drainage, clothing, soils, drainage, etc.

Perhaps a summary of what the German hygienic laboratories have been occupied with for the last five or six years, as indicated by the published reports and papers of those who have been working in them, will afford some indications as to the field which they have occupied.

First in number and extent, as just stated, come the bacteriologic investigations relating to anthrax, tubercle, typhoid fever, erysipelas, suppuration, diphtheria, pneumonia, cholera, and other diseases of men and animals.

Closely connected with these are the experiments on disinfection, and the testing of various forms of apparatus for disinfecting by steam or by dry heat.

Next come examinations of drinking-waters, of the effects of various impurities in waters, effects of lead pipe on waters, self-purification of running waters, changes in stored waters, etc. The effects of working in compressed air; the air of school-rooms, of assembly halls, of hospitals; the dusts and germs of the air, its changes by respiration and by ventilation, form another group of subjects.

Foods and drinks have occupied much attention—the quantity and quality of different articles that are most desirable—their adulterations, preparation, and preservation, including studies of meats, bread, milk, beer, wines, meat-extracts, etc.

Soils of streets, gardens, cemeteries, etc., with reference to their moisture, gases, and bacteria, seem to have received much investigation.

Clothing, various kinds of lighting, of heating, of plastering, and of floors and floor fillings, have kept some of the students busy. "Poisonous colors in clothing," "Bacteria in rags, canned foods, damp walls, shoes, ice," "Modes of disinfecting walls and floors," "How can a polluted well be purified?" are titles taken at random.

Just at present, research is being specially directed to certain minute animal organisms—the microzoa—such as are found in the blood in malaria and in the skin in certain diseases, and to immunity, especially to that immunity which may be artificially produced.

Experimental investigation is a slow process, and very uncertain in its results.

An experiment may be conceived which seems as if it would give important results. The experiment itself would require only a few moments or a few hours if all the apparatus were ready to produce the required conditions, and to record in terms of weight and measure the results obtained. But to make this apparatus in the best form, and to provide the means of recording, may take a year or more, and in making this preparation a dozen problems will come up to be solved by other experiments. You are pretty sure to discover something new, but by no means sure that it will be what you began to seek. Every discovery opens new questions and indicates new experiments, and the precise shape in which the work presents itself varies with place and season.

We cannot foresee precisely the demands which will be made upon us, or which we shall make upon ourselves, but we do know that we shall want some large rooms in which a dozen or twenty men can be at one time taught how to investigate, working under the eye of an instructor; and also a number of small rooms, each fitted for the work of one or two men who have attained a certain degree of skill, and are engaged in original research. In all of these rooms we shall at times need to use microscopes, gas-heating, and steam; there will be vapors and fumes produced; there will be delicate instruments scattered about, and the rooms must, therefore, be light, have abundance of gas, steam, and water, hoods and flues for conveying away fumes, and they must have plenty of fresh air without dust.

Many of the things that will be seen through the microscopes will be rapidly changing form, and we shall need pictures as well as descriptions of their different shapes.

The most useful drawings for our purposes are those made by sunlight, and, therefore, we want photo-micrographic rooms.

We shall wish to test the merits of various articles of house-equipment, such as different patterns of steam radiators, of traps, of sinks and closets, etc., and for this purpose we must have places where they can be fitted and put into use.

We must know what other investigators in other laboratories, and many places besides laboratories, have done and discovered, that time and effort may not be wasted. We must, therefore, have the books and journals in which these are recorded, which are already many, and coming rapidly. A small library and reading-room is therefore essential.

Much of the apparatus to be used must be either made or specially fitted and adjusted on the spot to meet special indications which it is impossible to foresee, and, therefore, we need a large workshop, with tools and appliances for working in wood, glass, and metal, and with power.

Let us now look for a moment at the plan of the building, and see how all these things, and some other needs, have been provided for. Entering the building from Thirty-fourth Street, on the west front, we find, on the main floor on our right, that part of the building which is more especially intended for the use of those not working in the research-rooms, but coming in from the Arts or Engineering and Architectural Departments of the University for special lectures and demonstrations. This contains a lecture-room and class-room, a room for preparing apparatus, etc., for demonstrations, a small museum-room, and the janitor's office. The lecture-room is fitted with various devices for experiments and demonstrations upon different methods of heating and ventilating assembly halls, such as school-rooms, churches, theaters, including means for propulsion or aspiration of air, for introducing and removing it at various levels, etc.

On the left of the vestibule are doors which separate the laboratory and research part of the building from the semi-public portion just described.

Passing through these, we have in front of us the

large chemical laboratory in which the students are to be made practically familiar with methods of examining air, water, foods, soils, etc. Next to it is the balance-room. Then come, on the north front, four special research-rooms, and on the south one research-room and a large drafting-room for the preparation of drawings and plans relating to heating and ventilation, house-drainage, sewerage, and water-supplies.

The radiators in the large chemical laboratory on the north front are each of a different pattern, and so arranged as to permit of the testing of the relative efficiency of each, or to permit of the substitution of other forms for such testing.

Ascending to the second floor, the outlines of which are the same as those of the first, we find, over the chemical laboratory, a large bacteriologic laboratory well lighted from the north, with working places for twenty students.

On this floor are five research-rooms, the photograph and photo-micrographic rooms with dark-rooms, the director's room and private laboratory, a library and a supplies-room.

The basement contains a large, well-lighted workshop, a combustion-room, a cremating furnace, a boiler-room, and an engine-room, and rooms for the janitor.

I will not go into details as to the purposes and uses of the various flues, hoods, pipes, and valves which you will see in every room. It is sufficient to say that they are designed not only for the convenience and use of the workers, but for experiments and demonstrations of many kinds.

The drainage of the building is on a double system, and is so arranged as to permit of the trial of new forms of traps, sinks, closets, etc. All pipes are freely exposed to view, and the different systems for cold water, steam, drainage, etc., are each painted a different color.

When you visit the Laboratory—as I hope you will do not only immediately after these exercises, but many times in the near future—you will see more clearly its arrangement than you can from a mere inspection of the plans.

As regards the external appearance of the building, opinions will, of course, differ. I will only say that it has been planned from within outward, which is the reason why it looks like a laboratory and not like a castle or a cathedral; and there is very little useless exterior decoration. Sky-lines and projections or recesses to obtain shadows have not received much consideration; space, light, and adaptation to the work to be done have been the points insisted on.

In many respects it affords a striking contrast to the library building in which we are assembled, and it is fit and proper that it should do so. The library represents the garnered experience and wisdom of the past; the laboratory is the workshop of the future. One is fruit, the other is seed.

In this connection I wish to express my high appreciation of the important work of the architects, Messrs. Collins & Autenrieth, of this city, in preparing the plans and specifications for this building and in supervising its construction, and especially to thank Mr. Collins for the many valuable, practical suggestions which he has made as the result of his careful study of our purposes and needs.

So much for the building and its contents as it is, and why it is as it is. The chief object of its existence is to fit a certain number of men from all parts of the country to investigate and solve the problems connected with the securing of the best health and vigor among our people.

We hope, also, that some increase of knowledge will be made here by the workers in the Laboratory itself; but the main point to be kept in view is to provide well-trained, scientific, and practical men for other fields of labor. Dr. Mitchell has said that the true rate of advance in medicine is not to be tested by the work of single men, but by what the country doctor is. So, also—and even more so—advance in practical sanitation is not to be measured by laboratory records, but by what health officers and sanitary engineers are able to accomplish.

Even now we *know* much more than we *do*, and the skilled sanitarian too often finds himself in the position of the unhappy daughter of Priam and Hecuba, who could foretell, but to no purpose.

This Laboratory is fortunate in being closely connected with, and in the immediate vicinity of, a great medical school, and of great hospitals. As was said before, one of the essential foundations of scientific knowledge of the causes of disease is minute and accurate diagnosis and pathology, and we are, therefore, in constant need of the best knowledge of leaders in these branches of medical science. The hospital is filled with specimens of the results of such causes, acting on the human body—from one point of view, Nature's experiments with poisons cunningly elaborated in the tissues of the body, or with viruses coming from without, upon blood and bone, muscle and brain. Much of the work of this new department will be connected with the results of these experiments.

The Laboratory is also fortunate in being located in a great manufacturing city, where the effects of different occupations, of trades dangerous or offensive by reason of dusts, or of vapors, or of waste-products, can be readily observed and the materials for study obtained. There is an immense field for a sanitary clinic here, and in the habitations, the streets, the water-supply, and the sewers of Philadelphia.

These clinics, however, cannot, as a rule, be reported for the press, either lay or medical, since to do so would, to a great extent, defeat their object; the great majority of sick houses and manufactories must be considered as strictly private patients, and their affairs held as confidential. In the case of public institutions, or of public nuisances, a somewhat different rule may apply.

Practical hygiene is to play an important part in municipal government, to secure the best form of which is now one of the most urgent questions of the day. Many of the questions to be decided by city officials as to water-supplies, sewage-disposal, etc., require expert knowledge to answer.

Of course, the subject of hygiene and the work of a University department devoted to the increase and diffusion of knowledge in sanitary science extend far beyond the experiments and demonstrations for which this Laboratory is specifically fitted.

Bacteriology, chemistry, pathology, physics, and medical and vital statistics give us the foundations, but

sociology and jurisprudence must also be studied in their relations to sanitation to obtain the best results.

It is in and to the home and the workshop that these results are to be applied, and he who aspires to be his brother's keeper must know how his brother lives.

Labor questions, education questions, maritime and inter-State commerce questions, and methods of municipal finance and government are all intimately connected with matters of personal and public hygiene; and economic consequences, as well as health, must be considered in the advice and regulations of the sanitarian.

I count it as fortunate, therefore, that there is a law school and a school of finance and political economy in this University to which the Department of Hygiene can look for advice and friendly criticism when these are needed, as they surely will be.

And now a very few words as to the needs of the Laboratory. First of all it needs men—men thirsting for knowledge, and fitted by previous training and education to come here and acquire that knowledge, not merely the knowledge that exists in books or that the teachers in this Laboratory may possess, but that which is yet unknown, the weight of that which no one has yet put in the balance—the shape, and size, and powers for good or evil of things the existence of which has not yet been demonstrated—men who will patiently and earnestly seek the answers to the questions, "what?" "when?" and "how?" in the hope that thus they may by-and-by obtain some light upon the more difficult problems of "whence?" and "whither?" even if they may never be able to answer "why?"

There are not many such young men whose tastes will be in the direction of these lines of research, and of these there will be very few who will have the means to support themselves while engaged in the work. We need, therefore, the means to help them in the shape of half a dozen fellowships, paying about five hundred dollars a year each, and granted only to those who give satisfactory evidence of capacity and zeal.

The second thing we want is a demand on the part of the public for really skilled, well-trained sanitary investigators and officials, such as we hope to send out from here; we want a market for our product; we want the legislators of this and other States, and of our rapidly growing municipalities, to be educated to appreciate the importance and practical value of such health officials, and to give the best of them employment.

Thirdly, the Laboratory wants the coöperation and assistance of sanitary authorities and inspectors, and especially of those of this city and State.

It needs to know from time to time what they are interested in and are working at, to have the opportunity of showing to its students cases of special interest—sick houses, localized epidemics, special forms of nuisance.

And, on the same principle and for the same reasons, it desires to have its attention called to special methods of heating, ventilating, and draining buildings, and especially public buildings, such as schools, hospitals, prisons, churches, and theaters, and to matters connected with the hygiene of manufacturing establishments and special occupations, methods of disposal of offensive or dangerous waste-products, of protecting workmen against dusts, gases, etc.

In short, we want to know how these things are managed by the men who have a practical interest in them; and if, in our turn, we can suggest improvements, we shall be glad to do so.

Fourth, the Laboratory wants a reference library as complete as it can be made, and always up to date. Many of the books and journals required must be purchased, and for this purpose a special fund is needed, but many of the works required can only be obtained by gift.

Thus, we want all the reports of boards of health—State and municipal—of municipal engineers, waterworks and water commissioners, park commissioners, etc.

We want the catalogues and circulars of all manufacturers of heating and ventilating apparatus, of plumbers' supplies and house fixtures, of electric and gas fixtures, of machinery and apparatus connected with water-supply and sewage-disposal.

We want copies of plans and specifications of large buildings of all kinds.

And these things can only be obtained through the aid and good-will of manufacturers, engineers, architects, and sanitarians all over the country; and this aid I venture to ask, feeling sure it will be granted by those who know what is wanted.

I will mention but one more special want to-day, and that is of means for the proper publication of illustrated reports and accounts of the work done in the Laboratory.

In the meantime we must be patient, and not too eager to touch the fruit of the blossom that is not yet blown.

In the chambers of this Laboratory are to be explored and tested some of the strangest and subtlest of the manifestations of force which surround and are within us.

Here we are to deal with problems of life and death; to seek to unravel some of the webs which bind and choke our children, and which make our strong men helpless, that we may for a time, at least, put these trammels aside, or sever them.

I dare not attempt to promise or to prophesy as to the work which will be done here, or as to the future of this new department of the University.

Those who are to be connected with it may not do the best that can be done, but at least they must do the best they can, and, if needful, give place to others who can do better.

Those to whom we owe this Laboratory and its equipment and endowment, have been generous and wise in their generosity, which has been in accord with the teaching of the son of Sirach, "Having grace in the sight of every man living, and detained not for the dead."

Death comes by many paths to one or other of the three porches of the microcosm through which he enters, and brings his poppy flowers to all doors soon or late; but if we knew that which we might know, and did that which we might do, he would be preceded by fewer heralds of suffering, and would arrive only when we were ready to be "hushed in the infinite dusk."

If "ye shall know the truth, the truth shall set you free"—not free from change, or from grief, or from the final passage beyond the veil, but free from causeless

fears, from unnecessary pain, from useless labor; and this is a part of that wisdom "which passeth and goeth through all things," and is "the brightness of the everlasting light, the unspotted mirror of the power of God."

ORIGINAL LECTURE.

LINEAR CRANIOTOMY.

A Clinical Lecture delivered at the Arapahoe County Hospital, October 9 and 16, 1891.

BY CLAYTON PARKHILL, M.D.,
OF DENVER, COLORADO;
PROFESSOR OF ANATOMY AND CLINICAL SURGERY IN GROSS MEDICAL COLLEGE; VISITING SURGEON TO ST. LUKE'S, DEACONESS, AND ARAPAHOE COUNTY HOSPITALS, ETC

THE boy to be operated upon to-day presents the following history, taken from the case-book of Dr. Eskridge, under whose care he has been for the last four weeks: L. A., four years of age last February, began having spasms when two days old, which lasted four days. After this he had whooping-cough for four months. One year ago he commenced failing. After the spasmodic seizures, he would be unable to get up for a week. These attacks occurred one or two weeks apart. Six months ago they became very severe and increased in frequency, often occurring two or three times a day. He would fall on the right side of the face, and the mother thinks that the right leg was affected. The examination of the eyes was made by Dr. Chase.

You see that the boy is fairly well grown and well nourished. The only abnormal condition that we observe is that the head is not developed in proportion to the size of the body. In other words, this child presents a condition known as microcephaly, or he is a microcephalic child. There are two theories regarding the beginning of this condition—one is that there is premature ossification of the cranial bones, thus preventing the proper development of the brain; the other is, that there is an imperfect development of the central nervous system, and that the cranial bones share in this condition, whatever may be the cause giving rise to it. The fact remains that the cranium is too small.

Lannelongue did the first operation for the relief of microcephalus. The procedure consisted in removing a narrow strip of bone from one side of the skull, making of the cranial bones two lateral flaps, which might be extended by the growing brain. He called this operation craniectomy. Keen has followed him, and has proposed the name of linear craniotomy, which I consider the better term for it. When the term "ectomy" is used in connection with an operation, it signifies a complete removal of the organ spoken of. In this operation we do not attempt to remove the cranium, but only make an incision into it and remove a small portion; so that I believe the term linear craniotomy, which signifies only a lateral incision into the cranium, much the better term.

The original operation has been modified in two instances by Wyeth and McClintock. They removed a strip of bone on either side of the median line, prolonged the incision laterally at each end of this longitudinal incision; and, in addition, made lateral incisions in the middle line toward the ears. They then separated the bones forcibly, thus widening the gap. In view of the mortality which has attended the operation thus far, I scarcely think that we are justified in making such an extensive operation. Horsley believes, that owing to the imperfect development of the nervous system, children are much more liable to shock than they would normally be, and so, with reason, advocates a single operation, as proposed by Lannelongue, and that is the method of procedure which we will adopt in the case before us. I might say, further, that during the time that this child has been in the hospital, every attempt has been made to develop his intellect by teaching, and it has been found impossible to add even the simplest word, the name of the commonest object shown to him, to his vocabulary. Had we found it possible to teach the child anything, it might have been wiser to attempt that method rather than to proceed to such radical measures as we shall institute.

This child has been carefully prepared for the operation. His scalp was shaved yesterday, thoroughly scrubbed with soap and water; afterward with ether, and finally with a solution of 1 : 2000 mercuric bichloride. The head was then bound up in a towel saturated with the mercuric solution, which you see is still in place. We will now remove that and measure the scalp. Ether has been used as the anesthetic and the child is now perfectly under its influence. From the inion to the glabella is ten and three-fourths inches. The biparietal diameter measures six inches. The circumference of the skull is eighteen and three-fourths inches. We will repeat the process of cleansing practised yesterday. Around the side of the head we will wrap a towel wet with a hot bichloride solution and under the child's head we will place a rubber bag filled with hot water. Mr. Horsley believes that it is possible in this way to lessen the shock. Fifteen minutes ago he was given five drops of tincture of nux vomica and a dram of whiskey to give still further support to the nervous system. And now we are ready to operate. I make an incision about three-fourths of an inch to the right of the median line, beginning at the anterior margin of the hair-area, and extending backward to within about one inch of the inion. We have comparatively little bleeding from the skull, as you will observe, because I have taken the precaution to have the temporal artery compressed. We catch the spurting arteries with forceps, and but little blood, as you see, has been lost. The periosteum is now exposed and I will make a single incision through it. I draw aside the periosteum in the same manner as I did the scalp, and we now observe the cranial bones. I apply a three-fourths inch trephine midway between the parietal eminence and the sagittal suture in the median line of the head. I remove the button of bone and you see I have not wounded the underlying dura mater. This bone is peculiar in that it is thinner than normal, not measuring more than one-eighth of an inch in thickness; and, again, it presents no diploic structure. With the Keen forceps I enlarge this trephine opening forward, making it taper to one-quarter of an inch at its anterior extremity, which corresponds with the scalp-incision. I prolong the opening backward in a similar manner, to within about an inch and a half of the inion. You will observe that the inci-

sion is elliptical in shape, measuring three-fourths of an inch wide at its widest point and tapering to either end, and having a length of about six and one half inches. The dura mater is bulging at the bottom of the wound and is rather dark-colored; otherwise apparently normal. With a pair of scissors I now remove a portion of the periosteum corresponding to the bony wound. I will irrigate the wound with a solution of mercuric chloride 1 : 3000, to wash away the fragments of bone left there. Drying it slightly with gauze, I sprinkle it with iodoform and am ready to close the wound, which we will do by means of interrupted silk sutures. I place these sutures one-half an inch apart anteriorly, and three-fourths posteriorly. You will observe that I have made no provision for drainage, but should necessity require it, the wound will drain between the sutures posteriorly, which have been placed so far apart. We will now again sprinkle the scalp with iodoform and apply an antiseptic dressing. The child has borne the anesthetic well and seems to be in good condition, and will now be sent to bed. From the time of the beginning of the anesthetic we have occupied about thirty minutes.

It is my privilege to present to you to-day the child upon which we operated one week ago, and we will dress the case now for the first time. You will observe that the child seems brighter and its appearance is better than before the operation, and he seems to more fully comprehend what is said to him. It is the opinion of the nurses and of the child's mother that his mental condition shows improvement. He has been decidedly less restless and nervous than he was before the operation, sitting sometimes for hours in his bed amusing himself with books in looking at the pictures. His physical condition has been exceedingly good. At 7 P.M. of the evening on which we operated, his temperature reached 100⅘°. From that time it began to decline, reaching normal the following morning. At no time since has it been above normal. He has slept well and has had a good appetite. I will now proceed to remove the dressing. I uncover the wound and you will observe that we have union by first intention. There is no swelling and not a sign of suppuration. I did not intend to remove the sutures for a day or two yet, but the condition is so good that I will take them all out. We will now wet the scalp with a mercuric solution, dress it with iodoform, and again apply our antiseptic dressing. Instead of the bandage to retain this in place I have had a cap made which answers the purpose much better. I will send the child back to its bed, and will tell you something of the other cases following operation.

Four cases have been operated on by Professor Keen. One died one and one-quarter hours after the close of the operation, from what was supposed to have been heart-failure. Another died four hours after the operation. The other two cases recovered and have shown mental improvement. The case of Gerster and Sachs died three and one-half hours after the operation, of acute anemia. Wyeth's case has greatly improved in intelligence. McClintock's case was reported too soon for the operator to decide whether there was improvement or not. Morrison's case showed decided improvement. And these comprise the operations that up to this time have been reported in this country. Horsley operated on two cases in England. One case died a few days following, from a condition of hyperpyrexia. The other case recovered, and showed very decided mental improvement. Lannelongue has reported twenty-five cases with but one death, and in those surviving the operation there has been improvement.

At the recent Congress of American Surgeons, at Washington, Professor Agnew, basing his opinion upon the operations that had been done in Philadelphia alone, decided that the procedure would "confer no credit on surgery." Taking into consideration the result of all the operations that have been done, I cannot agree with even that distinguished surgeon. Of these forty-one cases, five have died and thirty-six have shown mental improvement to a greater or less degree. I doubt whether any method of training that has yet been devised can take forty-one cases and show mental improvement in thirty-six of them. "But," you say, "five have died." Under methods of teaching, I believe you will find a larger number than that will fail to respond; and who can say that, for these little creatures, having no possibilities of intellectual development, death is not preferable to life?

The operation is yet new, and none of these cases have been under observation a sufficient length of time to know how much improvement we may get. The case that I have shown you is the first that has been operated on in the West, and we can only hope that it will continue to improve as much as it promises to do.

CLINICAL MEMORANDA.

A CASE OF AKROMEGALY.

BY H. A. HARE, M.D.,
PROFESSOR OF THERAPEUTICS IN JEFFERSON MEDICAL COLLEGE.

SINCE 1886, when Marie first described the curious disease known as akromegaly, a number of cases have been reported, and in some instances it has been possible to accompany the reports with the results of autopsies, which have quite constantly shown lesions of the pituitary body. In view of the numerous papers that have been published upon the subject in the last few months, I shall simply report this case without comment, in order to put it on record. The patient continues under my care, the disease progressing very slowly indeed.

A. M., a woman, aged twenty-five years, a Canadian by birth, has a good family history, and cannot remember that any of her relatives died of malignant disease. Three years ago, her menstruation became exceedingly irregular, stopping at times, and remaining absent for from four to six months. At this time she also noticed that vision began to fail, but more recently the failure has been rapid, and when she came under my care, December 12, 1891, she had become completely blind in the left eye. She states that the loss of sight began in the outer half of the left eye and gradually proceeded across the eye until the vision was entirely lost. Her right eye has also failed markedly in visual power since she has entered the hospital.

Physical examination shows a slight distention of the abdomen, with a general increase in the size of all of the members. There is a peculiar hump in the back from the last dorsal to the seventh cervical vertebra, and this

deformity seems to be characteristic of all well-defined cases. On the anterior surface of the chest, at the third interspace on the right side, there is a bulging half-way between the sternum and the nipple line, as large as an ordinary orange; it seems to be due to an increase in the length of the third and fourth ribs that project further than their fellows. There is no exostosis. Similarly, on the left side, the floating ribs are equally protruding, making a swelling as large as would be that produced by a fetal head if placed beneath the tissues. The hands are increased in size, and there is not only an increase of the connective tissues of the entire body, but also of the bony tissues. The nose is very much enlarged, and the face is massive in appearance. The limbs are also very much thickened, and her appearance is that of a large woman unequally developed. During the last three years, or since the beginning of her illness, she has gained about sixty-five pounds in weight, and I have been fortunate enough to obtain from her a photograph taken before she was ill, and another taken within the last two weeks. Engravings made from them are appended herewith. A comparison of these pictures indicates very thoroughly the great increase in dimensions that the patient has undergone. She has very distinct enlargement of the thyroid gland, but there are no associated circulatory disturbances. For the last few weeks she has suffered severely from neuralgia of the right temporal and supra-orbital region, which becomes very much worse at night, and at times sufficiently severe to prevent sleep. There have also been sharp pains in the extremities, and slight, varying pre-tibial edema. The appetite is good; the urine is rather scanty in amount. Examination of her right ear shows that she has lost hearing on this side, and that there is a chronic purulent otitis media. At the time of admission into the hospital the patient complained chiefly of pain in the left knee, loss of vision in the left eye, and of the absence of menstruation—indeed, she believes that the entire cause of her trouble is due to this latter disorder. She has suffered very much indeed from flashes of heat, which lasted ten or fifteen minutes, and then rapidly disappeared. At the angle of the left scapula, and extending to the vertebra, there is a spot where there is a peculiar itching, which changes to a prickling or tingling sensa-

FIG. 1.

FIG. 2.

tion upon pressure. About October 1st the patient had a hemorrhage from the lungs, and one week later suffered from an attack of epistaxis. The bowels are fairly regular.

Dr. D. D. Stewart, the chief of the nervous clinic of the Jefferson College Hospital, has been kind enough to send me the following account of the electric condition of the muscles and nerves in this patient:

FACIAL NERVE.

Faradic (Flemming's battery).

Switch on button 1, coil fully in: Response in upper facial muscles only, R. and L. side.

Coil out 2 in.: General response both sides.

Galvanic.

Right—Ca Cl c 2 M.a. . . . upper facial muscles.
" " " c 4 " . . . general.
Left— " " c 2½ " . . . upper facial muscle.
" " " c 5 " . . . general.
Right An Cl c 3 " . . . orbicularis palpebrarum.
" " " c 5 " . . . general.
Left— " " c 3 " . . . orbicularis palpebrarum.
" " " c 6 " . . . general.

UPPER EXTREMITY.

Faradic.

Shoulder and upper arm muscles: Switch on button 2, coil all in; electrode on motor points R. and L. side, very good response.

Extensors of forearms: Good response on both sides with switch on button 1, tube out 1½ in.

Flexors, forearm, respond with less strength of current. Current also diffused to them from extensor surface of forearm, causing response in flexors of fingers, with current too weak to cause contraction in extensors.

Galvanic.

Response produced with less current in flexors than in extensors of forearms.

In flexors, Ca Cl c 3 M.a.
" " " c 4 "
" An Cl c 8 "

ANTERIOR CRURAL NERVE.

Faradic.

Switch on button 1, coil out 2⅛ in.: Slight contraction in muscles supplied, on R.; on L. some contraction with coil out 1½ in.

Galvanic.

Right—Ca Cl c 10 M.a.; An Cl c 12 M.a.
Left— " " c 10 " ; " " c 12 "

SCIATIC NERVE.

Faradic.

Switch as before, coil out 2 in.: Contraction better on R.

Galvanic.

Right—Ca Cl c 10 M.a.; An Cl c 12 M.a.
Left— " " c 10 " ; " " c 12 "

The results of the electric examination indicate a normal qualitative response in all parts tested, but somewhat altered quantitative reaction—chiefly in the direction of delay, especially in the thighs.

The slow clonic response to the continuous passage of the faradic current noted some days before in the quadriceps extensor femoris on the R. was also seen in the middle finger of the R. hand in stimulating the extensor communis digitorum.

A study of the blood has been made by Dr. D. B. Kyle. The number of red blood-corpuscles was 4,700,000 to the cubic millimeter, with about 11,000 white corpuscles in the same space. The estimation of the hemoglobin by means of Fleischl's hemoglobinometer gave a practically normal percentage. The red blood-corpuscles are very much crenated and irregular in shape, many of them seeming to be poorly developed. They also appear to contain small particles of pigment; but it is impossible to decide this point positively. Owing to the peculiar formation of the corpuscle the black spot may be due to refractive conditions. This latter theory seems probable in view of the fact that on dissolving the corpuscles with distilled water these pigment-spots also disappear.

Dr. Hansell, the chief of the ophthalmologic clinic, has kindly sent me the following report of the examinations of the patient that he has made. It will be noted that a tumor of the pituitary body might very readily produce the ocular symptoms:

$$V = R, \frac{20}{XXX}; L, 0.$$

There is *total atrophy of the optic nerve* of the left eye with paralysis of the superior oblique (?). The muscle involved is doubtful on account of absence of light-perception. The disc is white, with a shallow cup.

The optic nerve in the R. is pale, with a shallow cup, but not including the entire disc. There is a small spot of pigment in the retina in the upper and inner quadrant.

The R. pupil is normal in its reaction to light and to accommodation.

The L. pupil does not act alone, but only in harmony with the movements of the R.

The field of vision for white is concentrically contracted, more marked upward, downward, and to the temporal side than on the nasal side.

There is a slight central color-scotoma, most marked for green.

Some three weeks after the first examination, vision in the R. was reduced to $\frac{20}{XXX}$ partly, and the field of vision had contracted.

A UNIQUE CASE OF POLYPUS OF THE CERVIX UTERI.

BY HANNAH M. THOMPSON, M.D.,
OF WILMINGTON, DEL.

THE following case of cervical polypus has been under my observation for about twelve years. The past seven years I have had almost exclusive charge of the case. The patient is an unmarried woman, and was about thirty years of age at the first appearance of the polypus, or of the diseased condition that preceded its development. Previous to this there was a history of failing general health for several years, and for three or four years preceding the typical growth, local treatment had been resorted to for a congested and retroverted uterus, with cervical catarrh and endometritis.

The cervicitis and endometritis improved under treatment, but there was no permanent restoration of the displacement or of the impaired circulation.

The date of the first appearance of the polypus is not clear, on account of the difficulty of early diagnosis.

After wearing a Hodge pessary for several months, without other treatment, a change for the worse was ushered in by a profuse hemorrhage from the uterus.

There was also associated great constitutional prostration, and especially nervous and cerebral irritation. Upon an examination at this time, the cervix presented a nodular, purplish appearance, suggesting a forming abscess; the external os was soft and velvety; the lining membrane of the cervix was sensitive to touch, bleeding excessively when touched. There was no other appreciable lesion, either in the cervix or in the uterine body, with the exception of the retroversion. The hemorrhage persisted for several months, with but short periods of cessation, and in spite of various alterative and astringent remedies. Dr. Charles H. Thomas, of Philadelphia, then had charge of the patient, and to his kindness I am indebted for an early observation of the case while a student at the Woman's Medical College.

Suspicious that the growth was of a malignant nature, Dr. Thomas, at different times, called two or more distinguished gynecologists in consultation. Malignancy was ruled out, but no positive opinion was offered.

One specialist suggested varix of the cervix as a possible diagnosis. During one of these consultations, the cervix was incised laterally through what appeared to be a hemorrhoidal or varicose tumor. This threw no light upon the case, except to reveal a very vascular condition. The hemorrhage was alarming at the time, and continued greater than before the incision, with little intermission, for several weeks.

Within the sinus that remained after the incision, fungous growths or projections now sprang up from time to time. These appeared to be the source of the hemorrhage. It was at this time also observed that at certain periods there was a soft, pulpy growth protruding from the external os. Under Dr. Thomas's treatment the patient improved in general health, but the metrorrhagia and other typical features of the case were only temporarily alleviated.

In the latter part of 1888, the case came more directly under my care, and I had then the opportunity of a more careful study of its obstinate features. There was still metrorrhagia—not so profuse as in the beginning—but I found that it was *periodic*, confined to about a week or ten days of the intermenstrual period, and that the nervous disturbance was greatest at this time. The *periodicity* of the different features was so marked as to attract my attention from the beginning. I found that exactly two weeks from the beginning of the monthly period there was an intermenstrual cycle as follows:

A very appreciable softening of the cervix; a flow of blood varying in amount (the past two years often greater than the monthly flow); slow dilatation of the external os; and in a few days a protrusion from the external os of a polypus, generally not larger than a good-sized pea. Accompanying this there was regularly a decided constitutional paroxysm lasting a week or more. This consisted of excessive nervous irritability, insomnia, with throbbing and distress in the head so great that the patient feared it would affect her mind. There was no imagination about this, as her appearance indicated suffering and painful nervous strain. These reflex symptoms constituted the most distressing feature of the case, as they yielded little, if at all, to medication. They were out of all proportion to the local lesion or pelvic irritation, and entirely different from the ordinary nervous symptoms of the monthly period. After the polypus protruded, the nervous symptoms abated, without removal of the growth.

The polypus would remain *in situ*, bleeding more or less for four or five days. It would then shrivel up and disappear, leaving the cervix, to all appearance, in a natural condition. An examination at this time would disclose nothing abnormal but a retroverted uterus. The week before, as well as about ten days or two weeks after menstruation, no growth was discernible and but rarely any hemorrhage after its disappearance.

I found, as had Dr. Thomas, that strong applications of iodine, carbolic acid, chromic acid, as well as positive electricity, would destroy the growth and occasionally prevent its formation for the subsequent month, but there was no stamping it out entirely. Surgical methods were tried with but little better success. Not only thorough dilatation and curetting of the cervical canal and internal os were tried, but at one time the base of the polypus was cut out entirely, and the underlying surface cauterized with strong acid. I found the polypus was attached by a broad pedicle—it seemed almost to be a part of the *substance* of the cervix—to the lateral wall of the cervix, midway between the external os and the internal os.

After the above operation, there was no return of the growth for two months. There was, however, some bleeding at each intermenstrual period. There was also partial relief from the peculiar reflex symptoms, but so much prostration followed the operation that it was decided not to repeat it. The treatment has since been simply palliative.

The polypus or polypi, for it sometimes appeared as if there were more than one, has continued to appear and disappear as described, with almost unvarying regularity, for at least *ten years*. The retroversion, which was always an additional cause of suffering and probably the starting-point of the disease, could not, on account of adhesions, be entirely corrected.

There is now, I think, a promise of cure with the establishment of the menopause. The first intimation of this change, three months ago, passed by without menstrual or intermenstrual period, but in place nervous disturbances occurred indicative of the menopause. The following three months the menses appeared regularly, as well as the intermenstrual growth, larger than at any time previous. There is now again a period of rest from both, showing conclusively, I think, that the termination of the menstrual cycle will break up the curious intermenstrual phenomena of this case.

What, then, are the peculiar features of the case?

1. A regular intermenstrual congestive paroxysm, with decided local and constitutional symptoms and the development of a lesion, extending over a period of at least ten years.

2. The obstinate nature of the growth—returning over and over again after thorough removal.

3. Its shrivelling up and disappearance without interference, after four or five days of maturity, followed by closure of the os.

4. The reflex symptoms, fully illustrating the effect of pressure upon or irritation of sympathetic fibers, are peculiar in their character and severity.

I find the literature upon this subject is exceedingly meager, throwing but little light upon the pathology of such growths. Some authorities describe a species of vascular polypus formed from development of the blood-vessels. Thomas says these are probably only a form of the cellular or mucous variety.

Emmett's "mucous polypi developed from enlarged Nabothian follicles," conform to the appearances in my case, but he says they are generally present near the menstrual period, and though occasionally returning, are curable. These are frequently met with in practice and are not generally obscure or obstinate. Hart and Barbour, in their classification of polypi, describe a form anatomically distinct from the mucous variety and which they name "pediculated cystic follicles." They are the result of chronic catarrh of the cervix, are bluish-red polypoidal projections, formed from obstructed Nabothian follicles, and are often accompanied by metrorrhagia. In my case there is no doubt but that the disease and the growths were cervical in their origin, as on microscopic examination they presented the characteristic columnar non-ciliated epithelium of the cervix, besides dilated glands.

The question arises, as in the case of all polypi, whether they were the cause or only the result of the inflammatory change.

Dr. Howard A. Kelly, who saw my patient in consultation more than once, was especially interested in the case, as he is engaged in making a special study of these intermenstrual phenomena. Dr. Kelly advised a thorough application of the galvano-cautery as offering the surest method of cure. It was postponed on account of the patient bearing operations badly, but I was about ready to give it a trial when the hopeful prospect indicated came to our rescue.

ERYSIPELAS APPEARING IN THE COURSE OF PUERPERAL PYEMIA.

BY W. REYNOLDS WILSON, M.D.,
OF PHILADELPHIA.

THE following case illustrates the probable identity of the cause of pyemia and that of erysipelas. There has been much discussion upon this point, and the report of this case may add some weight to the facts that have already been collected. The question as to whether in the present instance the erysipelas was an accidental condition can be decided only by a careful study of the history of the case, which is as follows:

The gravida, a primipara, aged twenty-three, was first examined on the 23d of September, four weeks before the time of her confinement. The record of her pregnancy shows nothing unusual, except that during the last two weeks she complained so much of pain in the lower part of her abdomen and on either side during exertion that she was withdrawn from the work that had been assigned her in the domestic arrangement of the hospital. Her labor was natural, the first stage lasting seventeen hours, the second two hours, and the third, terminated without the aid of artificial compression, forty-five minutes. There was no unusual loss of blood and no rupture of the perineum. The child weighed 8¾ pounds.

On the second day after confinement the patient suffered from a chill that lasted twenty minutes, followed by the subjective symptoms of beginning infection. Objectively, the fundus of the uterus was found on a level with the umbilicus and the uterus flabby and tender. The lochia were suppressed. The patient was put on quinine and an intra-uterine douche of 1 : 8000 bichloride was given. The temperature remained elevated, and intra-uterine douches, preceded by vaginal douches of creolin, were ordered to be given three times daily, and the ice-bag was applied over the fundus. On the evening of the fourth day, the patient suffered from another severe chill, followed by the appearance of tympany and great tenderness in the lower part of the abdomen. The intra-uterine douches were discontinued, and flaxseed poultices were used in place of the ice-bag. The pain was relieved by opium suppositories. During the course of the next two weeks, the patient suffered from an attack of pelvic peritonitis, the temperature ranging about 104°. During this time, the uterus, on examination, was found well contracted and held by adhesions toward the right side, so that it presented a hard tumor occupying the right hypogastric region. This tumor corresponded to a resisting mass that filled the right vaginal vault. The os was directed toward the left and showed a diphtheritic membrane extending into the cervical canal. On the morning of the fourteenth day, after the administration of calomel, the tympany subsided and the temperature fell to 102⅖°. The patient's general condition, however, remained unimproved. At the end of the second week of illness, a swelling of the left labium majus, accompanied by pain and redness, occurred. This disappeared in a few days, and was followed by a circumscribed patch of similar appearance on the right shoulder. This latter area was sharply circumscribed. During the next few days, similar patches appeared upon the thighs and in the tibial region. Their appearance was sudden and accompanied by sharp pain. The temperature remained elevated, and the patient showed extreme exhaustion of the nervous system.

These areas of infiltration were attributed to pyemic emboli, which were confined to the subcutaneous tissue. An examination of the heart and lungs revealed no signs of pulmonary or endocardial affection the result of emboli.

On the evening of the twentieth day, after a gradual defervescence, the patient's temperature rose to 102°; at the same time a swelling of the lobe of the left ear was noticed. This swelling rapidly increased, involving the ear, the malar and palpebral regions, and assuming a reddish and then a deep-purple color. The edge of the infiltrated area presented a distinct zone of demarcation. The character of this area upon its first appearance naturally led to the conclusion that the same cause was here effective as in the erythematous patches of the subcutaneous tissue noted. But gradually the appearance changed to that of a frank, characteristic erysipelas, accompanied by the usual systemic manifestations. This

attack subsided on the sixth day, with resorption of the infiltration and disappearance of the discoloration. This area, as well as those first mentioned, after the disappearance of the swelling, was the seat of furfuraceous desquamation.

The course of this case is of great interest in its pathologic aspect. In the first place, the infection was probably active from the beginning, the localized peritonitis being the expression of a general process, and the seat of invasion being the endometrium. The form of infection was no doubt dependent upon septic rather than putrid poisoning. This is proved by the absence of necrotic endometrium in the washings from the uterus and of offensive odor of the lochia. These facts are in accordance with what is known of the processes of infection from the endometrium. These processes are divided, according to the description of Bumm, under three heads: Putrid, localized septic, and general infective septic. In the first two a limiting zone of small-celled infiltration cuts off the affected endometrium from the muscular layer of the uterus, while in the last two no such zone is present and the infecting germs find their way into the lymphatic system without the intervention of any reactive process. The general infection in this case was complicated by the dislodgment of septic thrombi, which found their way into the circulation, producing the pyemic condition.

It remains to discuss the etiology of the erysipelas.

The similarity on the one hand between the erysipelas and the areas of embolic origin, considered as to the conditions under which they both appeared, lead us to infer that they were both due to the same cause. On the other hand, the extensive spread, the characteristic color and demarcation, and the course of the erysipelatous eruption warrant the diagnosis of true erysipelas. If we hold to the former inference, we would be adopting the more generally accepted view, namely, that of the identity of the streptococcus of erysipelas (Fehleisen) and the streptococcus pyogenes. The appearance, however, of the eruption upon the face instead of the genital region is contrary to this view, and might lead us to infer that the erysipelas was due to some other source of infection than that of the pyemia. This, however, is doubtful, as the history of the case shows that the patient before her confinement was not exposed to any source of infection, and the strict isolation that was observed during her illness made exposure after her delivery impossible.

PASSAGE OF A RENAL CALCULUS BY THE BOWEL.

By I. W. GOOD, M.D.,
of Spring City, Pa.

I was sent for on the morning of August 17, 1891, to see L. G., thirty-five years old, a married stove-mounter, of temperate habits. On my arrival I found the patient suffering from what he described as "cramps," from identical "spells" of which he had suffered frequently for quite a number of years.

The symptoms were those of renal colic, and indicative of the presence of the foreign body in the right ureter. The attack had set in three days previously, gradually increasing in severity. It had been noticed that the attacks were increasing in frequency, intensity, and duration, so that for some time the man had had in readiness opium in grain doses for the relief of the paroxysms.

The characteristic symptoms of the passage of a renal calculus were present: retraction of the right testicle; pain shooting from the right loin to the testicle of the same side and to the penis; considerable nausea; frequent micturition, with the escape of but a few drops of urine at a time. The pain was agonizing; the body was bathed in a profuse perspiration; the tongue was clean; the pulse between 56 and 60, soft and thready. There was no elevation of temperature; the bowels acted, the discharges being natural; the urine, on standing, deposited uric acid. The patient was measurably relieved by repeated hypodermatic injections of morphine.

Sodium benzoate was ordered in 15-grain doses, three times a day, with potassium bitartrate as occasion required to keep the bowels active and to favor elimination by the kidneys. Opium was given in grain doses every hour or half-hour, as required. The ingestion of liberal quantities of water and milk was encouraged. A warm hip-bath was ordered night and morning. The case pursued an uneventful course for several days, the patient not being entirely relieved. Thinking that possibly the manifestations might be malarial and neuralgic, several full doses of quinine sulphate were given, with the result of producing only the symptoms of cinchonism. As stated, the urine contained crystals of uric acid, but no blood.

The patient was able to arise from bed; the pain had somewhat abated; there was no elevation of temperature; the pulse ranged from 65 to 100; the appetite remained poor, and the tongue was heavily coated. Sleep could only be induced by opiates. At this juncture a tender spot, about one and a half or two inches in diameter, in the course of the right ureter, apparently near its entrance into the bladder, was detected, but no induration or redness was apparent. The patient was more comfortable with the right thigh somewhat flexed as he lay upon his back. The bowels were moved about every second day, and the stools were natural.

On the morning of the 29th I was hurriedly summoned, and found that the patient was entirely free from pain; the tenderness in the course of the ureter had in a great measure subsided; the man had enjoyed natural sleep during the night, and felt better in every respect; but he was alarmed by the character of his urine. On the morning of the previous day he had eaten a small piece of corn-fritter. His bowels were moved but a short time before he had sent for me, but unfortunately the stool was not accessible to inspection.

Shortly afterward he found that urination was obstructed, while there was a sensation of an accumulation near the urinary meatus; by straining and manipulation he at last expelled a grain of corn. The urine voided subsequently was found to have a horribly offensive odor and to contain fecal matter. Opium was ordered in sufficient quantities to check peristalsis, and in the hope of preventing the development of peritonitis. The patient was advised to lie on his back as much as possible, to reduce to a minimum the admixture of the contents of the intestine with the contents of the bladder, with the development of cystitis. An absolute milk diet was directed, and all excitement absolutely inter-

dicted. I was convinced that the calculus, by reason of its size, had become impacted in the ureter, which by adhesive inflammation had become attached to some part of the intestinal tract; subsequent ulceration had afforded the stone exit by the bowel.

I deemed it best to employ expectant treatment. The patient was much annoyed by frequent acts of micturition and by excessive tenesmus. The stools presented a urinous odor. For ten days more fecal matter continued to escape by the urethra. Opium suppositories and starch enemata were employed to allay the tenesmus. Following the enemata the urine responded to the tests for starch. Subsequently the urine became freer from fecal matter, though it contained pus and was highly ammoniacal. There were tenderness and irritability of the bladder, symptomatic of cystitis—for the relief of which sodium benzoate and turpentine were successfully employed. At the end of the third week of the symptoms of recto-ureteral fistula, the condition was in all respects much improved. At the end of the fourth week the patient sat up in a chair. For several weeks some tenderness persisted in the course of the ureter over the probable situation of the communication with the bowel. The evidences of such communication ultimately disappeared entirely.

MEDICAL PROGRESS.

Bronchiectatic Cavity due to Impaction of an Intubation-tube.—Sutherland (*Lancet*, No. 3569, p. 188) has recorded the case of a man, seventeen and a half years old, in which, after a blow upon the neck below the chin, pain developed, with difficulty of swallowing. In the course of a week the temperature rose, the voice became husky, and breathing became noisy and embarrassed. Suffocative attacks set in, with cough and the expectoration of considerable frothy mucus. Laryngotomy was performed, but afforded only temporary relief, so that subsequently intubation was practised. During a paroxysm of coughing, the string attached to the tube broke and the tube passed into the trachea. Efforts to remove the tube were unsuccessful. For a time the patient did so well that it was thought the tube might have been swallowed and voided by the bowel, but subsequently the symptoms returned in an aggravated degree. During a violent attack of cough, the patient perceived a sensation as of a moving body in the chest. He could only occupy the dorsal decubitus. Evidences of the formation of a bronchiectatic abscess appeared, for the relief of which pneumotomy was performed, but without the discovery of the foreign body. The patient progressively grew worse and died after repeated hemorrhages. At the autopsy, the intubation-tube—two and a quarter inches long—was found in the left bronchus, where it had given rise to a bronchiectatic abscess. The lumen of the larynx was narrowed. It is conceived that the primary injury had involved the pneumogastric nerve and had also given rise to a traumatic laryngitis. For three months the intubation-tube had lain in the trachea, where its presence was tolerated, until during a violent paroxysm of cough, the tube became dislodged, entering the bronchus and giving rise to the subsequent train of symptoms and fatal issue.

Resection of the Stomach for Carcinoma of the Pylorus.—At a meeting of the Royal Society of Physicians of Vienna, v. Hacker (*Wiener klin. Wochenschr.*, 1891, No. 47, p. 888) presented a woman, twenty-five years of age, in whom eight weeks previously resection of the stomach had been performed for the removal of an obstructive tumor of the pylorus. The patient had for nine months complained of epigastric distress, accompanied by pain and aggravated by taking food, and of characteristic vomiting several hours after meals, with emaciation. The vomited matter contained sarcinæ, but no hydrochloric acid. The tumor was palpable in the epigastrium and left hypochondrium; it was apparently from two and a half to three inches in length; no nodules could be felt. When the abdomen was opened, it remained doubtful whether the mass was carcinomatous or cicatricial. Several enlarged glands were detected in the omenta, and careful inspection disclosed the presence of a number of miliary nodules on the apparently smooth anterior surface of the tumor. By tearing the small omentum with dissecting-forceps and introducing a finger behind the stomach, it was found that the growth was not adherent posteriorly. After the resection had been performed, the mucous surfaces were approximated by continuous sutures, the sero-muscular coat by interrupted sutures and a few Lembert sutures. The operation occupied two hours. The subsequent course of the case was undisturbed. In three weeks the patient was able to get out of bed; in four weeks she was dismissed. Following the operation she gained four pounds in weight. On microscopic examination of sections of the resected portion of the stomach and of one of the enlarged glands removed, the growth was found to be a glandular carcinoma.

Local Anesthesia.—At a meeting of the Berlin Medical Society, Schleich (*Berliner klin. Wochenschr.*, 1891, No. 51, p. 1202) reported the successful performance of two hundred and twenty-four minor and major operations—including sequestrotomy, herniotomy, laparotomy, amputation of fingers, suture of the patella, radical treatment of hydrocele, extirpation of tumors, and nephrorrhaphy—by means of local anesthesia. It was found that but small quantities of cocaine were required for the induction of local anesthesia if considerable quantities of water were injected, so as to cause generous infiltration of the tissues. To obviate the pain of puncture, a spray of ether is first applied. The needle of a hypodermatic syringe is then introduced, parallel with the surface, beneath the papillary layer of the cutis, endermatically, and a small quantity (three or four minims) of a solution of cocaine (gr. $\frac{1}{10}$ to f$\bar{3}$j) injected. The procedure is repeated throughout the area to be operated upon, the little nodules formed mutually touching at their periphery. According to the depth of the proposed incision, layer after layer of tissue is treated in a like manner, even down to the periosteum, the bone, and the osteo-medullary cavity. A two per cent. solution of potassium bromide or of caffeine may be substituted for the solution of cocaine. The essential factor in the development of the anesthesia is the infiltration of tissue. The largest dose of cocaine required in any case in which it was employed was a little more than half a grain.

Cretinoid Idiocy with Pachydermic Cachexia.—At a meeting of the Medical Society of Hamburg, EISENLOHR (*Deutsche med. Wochenschr.*, 1891, No. 47, p. 1293) presented a girl, fourteen years old, without hereditary or family predisposition, who, it was stated, presented no abnormality until she was seven years old, when it was observed that there was a retardation of mental and physical development, together with an increase in the volume of certain parts of the body. In the course of time, the sides of the neck, the face, the forearms, and the hands became thickened and enlarged; fatigue was readily induced; intellectual activity became dwarfed; digestion was deranged; vomiting occurred and constipation developed. The girl at fourteen appeared no larger than a girl of seven; the head was large and brachycephalic; the nose was flat; the extremities were ungainly; the abdomen was prominent; the tongue was thick; the hair was red and rough; the teeth were imperfect. The skin of the face and hands was tense and doughy, presenting an appearance resembling edema, but suffused. Soft masses were palpable beneath the skin of the neck and in the supra-clavicular regions. The thyroid gland could not be detected. The urine contained no albumin. The fontanels were closed. There were no hernias. Intellectual development was defective. The patient's extent of language was small. Her appearance, however, was not idiotic.

Successful Treatment of Suppurative Phlebitis of the Internal Jugular Vein and the Lateral Sinus.—PARKER (*Liverpool Medico-Chirurgical Journal*, No. 22, p. 44) has recorded the case of a man, twenty-five years of age, who for eleven years following an injury in the region of the left ear, presented symptoms of suppurative otitis media, with perforation of the tympanic membrane. Symptoms of suppurative phlebitis of the left lateral sinus and internal jugular vein, with double optic neuritis, developing, an incision was made in the mastoid and infra-auricular regions, and the mastoid process was opened. A clot was found in the facial and jugular veins, extending into the lateral sinus, which was occupied by greenish purulent lymph. Ligatures were applied to the veins on either side of the thrombi, and the intervening portions excised. The lateral sinus was partially scraped. Hemorrhage was controlled by a plug of antiseptic wax. The symptoms disappeared for two days after the operation; then the temperature rose to 103°. The wax plug, with some accumulated pus, was removed from the sinus, and the mastoid cells were irrigated. For nearly a week the temperature continued to oscillate between high figures, but finally subsided, the case ultimately progressing to a favorable termination.

THERAPEUTIC NOTES.

Benzol in Influenza.—ROBERTSON (*British Medical Journal*, No. 1621, p. 171) recommends the employment of benzol in the treatment of influenza—as he has likewise found it useful in the treatment of whooping-cough. The symptoms of the disease are speedily and favorably influenced, and pneumonia seems to be prevented. Benzol can be dispensed in capsules or in mixture, in doses of three minims for children and five minims for adults, every two or three hours. The following formula may be employed:

℞.—Benzol. pur. . . . . ♏lxxx.
Spts. vini rect. . . . f℥ss.
Spts. chloroformi . . . f℥iij.
Mucilag. tragacanth. . ad f℥viij.—M.

S.—A dessertspoonful or a tablespoonful at a dose, to be taken in lemonade.

Tuberculin in the Treatment of Leprosy.—KALINDERO and BABES (*Revue de Médecine*, 1891, No. 10, p. 817) have reported the employment of tuberculin in the treatment of eleven cases of various forms of leprosy. They found that the general reaction set in about twenty-four hours after the injection. Sometimes a second and a third reaction followed on successive days. Rapid repetition of the injections was followed by cumulative action. In some cases of tuberculous leprosy, small doses were followed by intense and protracted reaction. Local reaction was slight or wanting; exceptionally, it was intense and extensive; it manifested itself by injection of the infiltrated areas and the slow formation of crusts, with desiccation; the general condition was improved, though weakness resulted.

Potassium Permanganate as an Antidote to Phosphorus.—At a meeting of the Royal Society of Physicians of Budapest, BOKAI (*Deutsche medicin. Wochenschrift*, No. 47, p. 1294), as a result of chemical investigation and experiments upon animals, commended from one-fifth to one-third of one per cent. solutions of potassium permanganate as an antidote in cases of poisoning by phosphorus. Phosphorus in the presence of potassium permanganate is converted into innocuous orthophosphoric acid in the stomach, with the development of manganese chloride. Poisoned dogs thus treated were saved; untreated dogs died. Even one per cent. solutions of potassium permanganate exerted no injurious effect upon the coats of the stomach.

For Sore-throat.—

℞.—Cocainæ hydrochlorat. . gr. viij.
Acid. carbolici . . . ℥j.
Glycerini . . . . f℥iv.
Aquæ rosæ . . . ad f℥xij.—M.

S.—To be diluted with an equal quantity of water, and used alternately as a spray and gargle. WHITLA.

For Tapeworm.—One of the best remedies for the expulsion of tapeworm from the intestinal canal is the oleoresin of male fern. After the usual preparatory treatment by low diet and catharsis, two drams of the oleoresin of aspidium may be whipped up with the yolk of an egg and peppermint-water, and syrup added to make two ounces; the whole being taken in the morning, on an empty stomach; and, if necessary, followed by a purgative.

For Incontinence of Urine.—

℞.—Tinct. nucis vomicæ . . f℥vj.
Ext. damianæ fl. . . . f℥ijss.
Glycerini . . q. s. ad f℥iv.—M.

S.—℥j three times a day, after meals, in a wineglassful of water. WHITLA.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,

PHILADELPHIA.

SATURDAY, FEBRUARY 27, 1892.

THE RETAIL DRUGGIST.

FROM a widely-distributed advertisement we quote the following paragraphs taken from the *Druggists' Circular* for September, 1890:

"COUNTER-PRESCRIBING.

"In this and other States there are very stringent laws to prohibit counter-prescribing by druggists, and as our medical brethren have spies constantly on the lookout, and a number of arrests have been made, it is of the greatest importance that all pharmacists should be on their guard. There is, however, no law under which a druggist could be arrested or fined for selling a friend or customer what they called for, and in order to meet this difficulty a little book entitled *A Medical Manual for the Treatment of Simple Diseases* has been carefully prepared.

"This work, which is carefully arranged in alphabetical order, gives the patient all the information he would most likely ask the druggist for, and which the pharmacist is not now in many places allowed to supply orally.

"The publication of this useful and valuable book is one of the most important events in the drug trade that has transpired in many years."

Following this announcement, there are full directions as to securing the book at the rate of one cent each, the same retailing "at 25 cents, this price being so printed on it."

Now, it may be said that this is really so contemptible as to be beneath notice; that too much splutter has been made about the counter-prescribing of druggists; that the physician ignores the pharmacist's side of the question, etc. But taken in connection with other aspects of the drug business it may be answered that it is easy to make a mistake in the attitude of disdainfully ignoring such evidences of the degradation of a once noble profession.

Because, taken up in a large way and carefully examined, the multiple evidences of this degradation are but too painfully patent. The worse than commercialization of the standing of the retail druggist is a sorry fact. Here and there—one or two in every city, perhaps—there remains a druggist respecting himself, his own profession and that of medicine, who, refusing to turn his store into a "soft drink" saloon or junk-shop, preserves the tradition of better days and the isolation of dignity in distress. His smart neighbor, who has adopted the modernized fashion, smiles derisively at the old-fashioned way, and slowly crowds the antiquarian out of existence.

And the new-fashioned way—What is it? Nay, rather should we not ask, What is it not? To attempt an enumeration of the multiplicity of articles or classes of articles, the Noah's ark of odds and ends, would tire an auctioneer. The ten-thousand-dollar soda-water fountain is the *pièce de résistance*, fast progressing to the lunch and coffee counter, and to mysteries beyond the comprehension of the uninitiated. Queensware, bric-a-brac, and infinite *olla podrida*, dispute with patent medicines galore the places of honor. Find the prescription department if you can and dare!

Some time ago THE NEWS pointed out certain reasons why physicians should dispense their own medicines. The considerations then adduced looked only to the good of the medical profession and the duties of the physician to the patient. But observation of the position of self-degradation of the druggist emphasizes the advice. Certainly any protest of the druggist is summarily stopped by—

1. The common practice of counter-prescribing and the suspicion of sneak authorized by the foregoing quotation from the *Druggists' Circular*.

2. The farcical commercialization of the profession and the omnium-gatherum type of the modern fizz-water-buffet-tobacco-shop-queensware-jewelry-what-you-please drug-store.

3. The patent-medicine disgrace, in which crime against civilization the druggist has become a chief abettor and agent.

4. The adulteration and impurity of the drugs kept, as proved by the late investigations of the New York State Pharmaceutical Association.

There is another reason that will in the future continue more powerfully to hasten the downward progress of the druggist's calling as a learned profession. This is the gathering of the art of compounding drugs into the hands of the manufacturing chemist, and the resultant concentration of this function under the control of a few large firms. Machinery, centralization, systematization, and the progress of pharmacology, have made it possible to compound vast quantities of almost every conceivable prescription with an accuracy that is greater and at far less expense than is possible in the case of a single prescription for a single patient. The wholesale manufacturer, moreover, passes by and over the retail druggist, supplies the physician directly, and the physician, finding it to his own benefit as well as to that of his patient, will more and more supply his patient at first hand.

There may be sad disadvantages in the outworking of this tendency, and many serious questions and difficulties will doubtless arise. It is barely possible that the better class of pharmacists may refuse to follow the drift of tendency, and heroically stemming the tide, in part and to a certain extent, rescue their calling from threatened degeneracy. It is doubtful, however. Young men with the capacity and high-mindedness to uphold the elder tradition will hardly ship on a vessel so rotten-timbered and strained. Already the profession of pharmacy is considered but a temporary makeshift, a half-way house. The course in pharmacy lessens the regular medical course of study by one year. It would be interesting to know how many matriculants of medical colleges have first served in the drug-store.

OPENING OF THE INSTITUTE OF HYGIENE OF THE UNIVERSITY OF PENNSYLVANIA.

THE NEWS herewith presents its readers with the Address of DR. BILLINGS, delivered last Tuesday, at the opening ceremonies of the Institute of Hygiene of the University of Pennsylvania.

Whether intentional or not, there was a subtile and genuine significance in choosing February 22d as the day for inaugurating the Institute. In its final analysis and outcome, Democracy, of which the United States is certainly the champion and example, must mean health. That, of course, means health for all, because, as science now well knows, there can be no certain and enduring health for any class or any person unless the health of the lowliest and the remotest citizen of the country —nay, of the world—is also assured. No science better than medicine illustrates and proves the great doctrine of the solidarity of the human race. Politically, that is the lesson of democracy, and it therefore argues well for us that so early in our country's history, by boards of health—municipal, State, and national—and by institutes of preventive medicine, we are manfully grappling with our tasks and duties to our fellow-men, present and to come. At first blush it would seem a shame that, as a community, we do not recognize the obligation, but stupidly wait for private generosity and institutional self-sacrifice to do that which Government should long since have done. DR. BENJAMIN LEE ironically referred to this sad aspect of the matter, the aristocratically governed peoples of Europe being protected by a thousand wise safeguards against adulteration of foods, pollution of water, etc., and enjoying myriad hygienic advantages over ourselves. But it should not be forgotten that as yet we are only experimenting with civilization and government, that, intoxicated with our own youth and surplusage of strength, we leave the rascals to cultivate the art of plunder, instead of attending ourselves to the serious art of governing. If, in this mood, every city and State had a laboratory of preventive medicine, Hygeia would probably soon become a very leprous goddess. The political boss and the scientist would be a very mismatched pair. For a considerable time we must yet await the recognition, on the part of the public, of its duty both to preventive medicine and to itself, and also the possibility of successful realization of any practical work in that field. The great difficulty in getting the paltriest appropriation from the politicians proves how far we still are from communal action. In the meantime, all discriminating minds should help pay the debt of gratitude the City, State, and Country owes to the nobly beneficent men who have presented the people with such a Laboratory, and to the great educational institution that guarantees its work and future usefulness. A fuller endowment is still needed, and more important even than endowment is coöperation and practical helpfulness on the part of all.

THE MUTUAL AID ASSOCIATION OF THE PHILADELFHIA COUNTY MEDICAL SOCIETY.

NONE that will read these lines can be ignorant of how precarious is the professional income of medical men, and how few are the opportunities of accumulating money in medical practice. Many will be able to recall the cases of practitioners that during life had labored arduously and, removed prematurely or in old age by death from the midst of their families, had left those that had been dependent upon them without adequate means of support. Recognizing these facts, associations have been organized in England and in the United States with the object of providing for indigent widows and children of deceased medical men, as well as for such physicians as by accident or adversity have lost their own means and powers of support. In the spirit of this movement and with these nobly philanthropic motives has the Mutual Aid Association of the Philadelphia County Medical Society been organized. As the president of the Association has well said, membership constitutes not insurance, but charity. It is hoped to establish a permanent fund of a hundred thousand dollars to be derived from the philanthropic, both within and without the medical profession. Members of the County Medical Society may become members of the Mutual Aid Association by paying an initiation fee of five dollars and an annual fee of five dollars for ten years or ten dollars for five years; by paying fifty dollars in one sum they become Life Members. Anyone that pays a hundred dollars becomes a Benefactor. In suitable cases, as soon as a sufficient fund has been accumulated, an annuity of four hundred dollars will be paid to the widows of members and one hundred dollars to each child. The Association is most economically conducted. It has practically no expenses. All of its income is devoted to the Permanent Fund. Every physician should indorse the work of the Association by at once becoming a member or by contributing directly to the Permanent Fund. The general community can in no better way testify to its appreciation of the labors of a self-sacrificing profession than by meeting with a full and generous response its appeal for funds in a noble cause.

The members of the profession in every part of our country should establish similar societies.

In evidence of the practical working of the movement under consideration we refer to the report presented at the annual meeting of the subscribers to the British Medical Benevolent Fund, held in January, according to which, during the year 1891, nearly $9000 was distributed in grants among 159 persons and a like sum among 99 annuitants.

MEDICAL SOLIDARITY OF THE RACE.

PHILOSOPHERS and moralists have long been in the habit of emphasizing the great fact that the life of the world is a unit, and that all biologic facts and phenomena are mutually interdependent. The profundity and reality of the truth have been obscured by the vagueness of the generalization. Civilization has often given convincing examples of the fact, but there is none more striking than the conveyance of contagium along lines of travel. Before the development of the marvellous means of quick intercommunication, there was less danger of the transfer of disease-germs than now, when localization of disease of any kind grows more and more difficult. That we have to become responsible for disease generated ten thousand miles from us, among people whose national names and languages sound most strange to our ears, is a fact that comes vividly before us as we consider the typhus fever pest brought to our homes by the poor Russian refugees. One steamer alone has sown ninety-six cases of typhus among our Eastern cities. The greatest energy and severest caution are demanded. The physiologic sins of these far-away folk are visited upon us. We at once become interested in the most lively way in the social and economic life of an oriental and semi-barbarous people. It becomes our duty and self-interest to see to it that the bad life *there* is made more healthy and normal, in order that the better life *here* be not morbidized.

It also cannot be held an unjustifiable extension of the thought that the application of the principle of the solidarity of the human race is not limited to aspects simply physiologic or pathologic. Pathology and pathogeny are preaching the preacher's text more powerfully than he could prophesy or foresee. The brutal edicts of Tsars and race-hatreds forcing famishing men to cast themselves by thousands upon our shores, bringing with them malignant disease to scatter broadcast amongst us, are also consequences flowing from other factors than physiologic ones. We become interested in lessening those governmental, aristocratic, and irreligious deviltries that make up much of what is ironically termed Russian civilization. Whether by huge portfolios of petitions, by magazine publications, or

by the persistent effect of national diplomacy and influence, democratic America is vitally concerned in curing, civilizing, and democratizing sick, barbaric, and tyrannized Russia.

IN NEW YORK

THEY have a medical periodical, *The Post-Graduate*, the anonymous editor of which is deeply interested in his own "great medical discovery ignored," consisting in the important pathogenic fact that at the very finest restaurants of New York the cooking is bad, the table and food poorly served, etc.; just around the corner more "toothsome" food is to be had. In this and other medical matters the editor breathlessly seeks to be pert rather than pertinent, curt rather than courteous, and he evidently is thoroughly satisfied with his success. His devotion to the interests of the medical profession is shown by a defence of the hospital-charity abuse, and his knowledge of medicine by the ludicrous assertion that a mydriatic is not at all necessary for the accurate estimation of errors of refraction; the use of a mydriatic, he asserts, being an "ancient practice."

It is the commonest experience of the ophthalmologist that his patients remain strangely unconscious of high degrees of astigmatism and ametropia. How frequently likewise we stumble on the analogous illustration of mental astigmatism, emotional myopia, moral strabismus, or other like sorry type of psychic ametropia, amblyopia, or restricted field —all with delicious innocence of incongruity; in the same way that humor is most perfect when the comic source is self-confessedly most serious and goes about with most gothically arched eyebrows.

But in New York, as we know, they have also many sincere men and good physicians; from them, if desired and if possible, the excellent lesson might be learned that flippancy is not irony, that conceit is not good manners, and that, exceptionally, post-graduate wisdom may be undergraduate nonsense. This is also "*very, very true.*"

In sword-lore there is a legend of a blade so fine and so sharp that, with a good blow, a man's head could be severed from his body and not be displaced, and the man remain in ignorance of the fact—so long as he kept right still and did not cough. It would seem that fatuous superciliousness may clumsily perform hari-kari of this peculiar and extreme kind in ignorantly attempting to wield the dangerous weapon of modern medical criticism. We write with the kindliest intent, and only to caution our hari-karicaturist that after such superb swordsmanship there is great danger in coughing.

SELECTION.

TYPHUS FEVER IN NEW YORK.

THE most serious outbreak of typhus fever that has occurred in the country for many years, became known to the health authorities of New York late on the night of February 11th, and on the following day no less than fifty-eight cases of the disease were discovered. On January 30th the French steamer "Massilia," of the Fabre line, arrived with 717 steerage passengers. Two hundred and fifty of these were Russian Hebrew immigrants who were aided by funds provided by Baron Hirsch, and they were first transported from Odessa to Constantinople, whence they hoped to be able to go to Palestine and settle. Being disappointed in this, through the action of the Turkish authorities, they came to Marseilles, where they embarked on the "Massilia," together with a considerable number of other immigrants of various nationalities. The steamer on January 1st took on board more than 200 Italians, and on January 12th she sailed from Gibraltar. On the ship's arrival eleven passengers were ill, three of them with what was believed to be typhoid fever, but which, as the sequel shows, was undoubtedly typhus.

On the day following, February 12th, eleven additional cases were discovered among the Russians. Every effort was made to trace the Italian and other immigrants who came on the "Massilia," but it was found that many of them had left the city. On February 13th, five additional cases of typhus were found among the Russians from the "Massilia;" February 15th, seven more cases; February 16th, six cases at Oakdale, Mass.; and each day is adding to the list. There are, at time of writing, eighty-nine cases at North Brothers Island.

The whole country is more or less alarmed and disturbed, and really in a certain measure endangered by the living freight which this steamer has been allowed to land upon our shores after it had been refused the hospitality of the intelligent Turk.

We have thought it worth while to put together the main facts in the case as an illustration of the daily folly which we, as a nation, are permitting to be committed in the beautiful name of freedom, to the relief of other countries, the profit of a lot of steamship companies, the gradual degradation of our population, and the positive diminution in the safeguards for life, liberty and the pursuit of happiness which those already living here would like to be assured of. We open our doors to squalor and filth and misery—which mean typhus fever—and we admit leprosy, almost as if these things were blessings in disguise.

The reports of the Treasury Department show that for the last six months of 1891 the number of immigrants coming from Russia (Poland excepted) in those months was 46,710, as against 20,934 in the corresponding months of 1890. The whole number of immigrants was greater in 1891 than in 1890 by about 100,000, and

nearly half of this increase is ascribed in the reports to Russia and Poland.

As sanitarians, with this text before our eyes, we desire to add our indignant protest to that expressed by the eminent statistician, Gen. Francis A. Walker, in a recent lecture against the results of our immigration laws. There are times when charity should begin at home.—*Boston Medical and Surgical Journal.*

CORRESPONDENCE.

CHICAGO.

Dr. W. M. Tomlinson—Improvements in the Northwestern University—The Alexian Brothers' Hospital—New Laboratory of Rush Medical College—Dr. Bayard Holmes on Infectious Filth Diseases.

DR. W. M. TOMLINSON, Registrar of Vital Statistics in the City Health Department, has resigned that position after seven years' service, to devote his entire time to the practice of medicine. Dr. Tomlinson was appointed by Mayor Harrison in his last term, and was so efficient in the discharge of his duties that he has stayed through Republican and Democratic administrations until the demands of his private practice have compelled him to give up his official position.

Many new buildings are needed for the various departments of the Northwestern University. The medical and pharmaceutical departments are to be the first schools favored with a new structure. The plans for a $100,000 building have been accepted by the board of trustees of the university, and when the Fall term of 1892 commences the structure will be ready for occupancy.

The site of the new building, which will be occupied by the medical and pharmaceutical departments, is located on Dearborn Street, sharing the block of 450 feet between Twenty-fourth and Twenty-fifth Streets with the new Wesley Hospital. The plans are for a structure of stone and brick, 110 by 105 feet ground dimensions, and its four stories and basement will make a total height of 75 feet. The entire department of pharmacy will be quartered in the new place, and all the laboratories of the School of Medicine will be situated here. At present the University Medical School is located at the corner of Prairie Avenue and Twenty-sixth Street. This building is to be remodelled, and the school will continue to use it for college purposes after the completion of the Dearborn Street building.

The twenty-fifth annual report of the Alexian Brothers' Hospital shows 2109 patients admitted to the hospital in 1891, and 1408 sent out as cured. Only 150 patients died. A large amount of charity work was done during the year, there being 827 charity patients treated. Dr. A. J. Baxter, of the surgical department, has retired; and Drs. F. Henrotin and J. B. Murphy have been appointed surgeons. Drs. J. H. Hoelscher and F. W. Rohr have been appointed to duty in the medical department.

Rush Medical College is to have a biological and pathological laboratory, to cost $50,000. The faculty has raised the necessary funds, and the laboratory will be built during the coming summer, and be ready for occupancy in the Fall. One of the most important departments in the laboratory will be the department of bacteriology. One of the faculty stated that the position of director of the laboratory would be filled by a well-known European bacteriologist. At a recent meeting of the faculty replies to letters sent out to famous European specialists inviting them to suggest some celebrated bacteriologist for the place were read. From the names suggested the faculty will, at a subsequent meeting, select a man who has a world-wide reputation. The bad sanitary conditions in many of the large cities long ago demonstrated the wisdom of making the study of bacteria a feature of the course at Rush, and the bad sanitary condition of Chicago was one of the reasons urged for the establisment of the laboratory and a professorship of bacteriology.

Dr. Bayard Holmes, in a recent lecture before the Evolution Club on "The Evolution of Disease," said: "The infectious filth diseases are the most destructive diseases that man is heir to. Of all these filth diseases we are perhaps most interested in typhoid fever. Typhoid fever is due to a bacillus, rather shorter and thicker than the bacillus of tuberculosis. The microorganism lives readily upon all kinds of filth, animal and vegetable material, and even in water which contains a small amount of dissolved organic substances. It has been found in drinking-water and in ice, and when it grows in sufficient abundance it gives off a by-product called nucleine, which, when taken into the system, after the microbe itself has been killed, produces a transient form of the typhoid disease.

"Diphtheria is due to a bacillus that is found only upon the mucous membrane of man and the lower animals. It is saprophytic or putrefactive in that it grows readily upon all nutrient material, such as potatoes, bread, paste, and gelatin.

"Cholera is a filth disease due to the invasion of the body by a bacillus which resembles the other putrefactive bacteria. The cholera-germ grows readily in or on animal or vegetable matter, and in water that contains only a small amount of organic substance in solution.

"Malaria is due to infection of the blood with a living animal parasite called the plasmodium of malaria. It belongs to the order protozoa. This parasite inhabits the circulating blood, and can be seen moving about in the red blood-corpuscles themselves at certain times in the course of the disease. This organism has not been grown on any artificial culture media, though it is supposed to be an inhabitant of marshes and wet, undisturbed soil. There are a number of other filth diseases —cholera infantum, for example—but it is tiresome to hear of so many. They are all alike in being due to the infection of the tissues of the body, or the invasion of the organs of the body, by microörganisms that lead lives wholly independent of man, or live only partially dependent on man as a messmate. That is to say, they are due to organisms not necessarily parasites. If man insists on drinking out of his cesspool or catch-basin he will expose himself to yellow fever in Vera Cruz, to cholera in Calcutta, to malaria in New Orleans, and to typhoid fever in Chicago.

"In regard to the prevention, extermination, and amelioration of the suffering from these diseases the evolutionist and philosopher has much to say. The chronic

infectious diseases can be exterminated by an understanding of their origin, their source and method of contagion, and proper segregation of those invaded by the parasite. The vaccination of Jenner points to the remedy for the acute infectious disease. The filth disease, the concomitants of an imperfect civilization, will be exterminated by education and by cleanliness. In our grandfathers' day the itch went around every winter. It was a theme of polite conversation a few years ago. They spoke then of having the itch as we speak of having typhoid. It will soon become as embarrassing to say, 'I have just recovered from an attack of typhoid,' as it was to say, 'I am just getting rid of the itch.' As the family was the unit that perpetuated and exterminated the itch, so is the community the unit that perpetuates and must exterminate the filth diseases.

"It is possible that all the existing diseases are not yet recognized by the medical profession, but none not now existing will ever persecute man. Among the filth diseases, however, new diseases may arise. In the enormous accumulations of filth in the lake, extending a mile out and up and down the shore for twenty miles opposite this city, growing a few inches deeper year after year from the deposit of our enormous sewerage, some predominant saprophytic microörganism producing a very noxious ptomaïne may become partially parasitic, as the typhoid bacillus has, and give rise to a new disease endemic. If we can afford to have one or two thousand die in our city each year of typhoid, and about five or six times as many sick for two months each, we can afford to continue to pile up this filth in the bottom of the reservoir of our water-supply. There was a time in the history of the city when the doctors claimed that the wells were contaminated with typhoid, and urged that they be closed. Again those fanatical fellows besought the honorable guardians of the city's health to stop taking water from the river and from the lake at the foot of Randolph Street, and now some suggest that pure water cannot be obtained long even at the four-mile crib if the sewers are allowed to empty their contents into the lake.

"Let us stop our hysterical emotions and sit down and think. If a little education will exterminate the chronic infectious diseases, and education and cleanliness the filth diseases, let us go to work to educate the people. If the pests of childhood, the acute infectious diseases —scarlet fever, measles, and whooping-cough—can be ameliorated and practically exterminated by some form of preventive inoculation, let our benevolent people stop building hospitals and libraries for a year or two and build some laboratories for the study of preventive inoculation. The day is not far distant, in my opinion, when the acute infectious diseases will be exterminated; when a terminating inoculation will be practical for tetanus, diphtheria and pneumonia; when a great city will cease to make a cesspool of its water-supply and will spend less for its department of charities than for its department of health. The age of emotion will merge into the age of reason."

Orchitis following Influenza.—BRISCOE (*Lancet*, No. 3569, p. 192) reports the case of a laborer, thirty-two years old, in which, after an attack thought to have been influenza, orchitis developed, without other complication.

REVIEWS.

THE PRINCIPLES OF BACTERIOLOGY: A PRACTICAL MANUAL FOR STUDENTS AND PHYSICIANS. By A. C. ABBOTT, M.D., First Assistant, Laboratory of Hygiene, University of Pennsylvania, Philadelphia. With illustrations. 8vo, pp. 263. Philadelphia: Lea Brothers & Co., 1891.

AMERICA has realized that the science of bacteriology is established upon a permanent basis. The evidence of the fact consists, not in the acceptance of the germ-theory of disease, but in the organization of departments for instruction in the methods of bacteriologic research. With this advance comes the necessity for suitable text-books, of which there are already numerous good ones, both in English as well as in foreign languages; but each teacher has some peculiar method of exposition, and finds that he can best reach his pupils if, in addition to his personal teaching, he can place in their hands a book of reference, so that the practical demonstration may be supplemented and fortified by liberal reading.

Dr. Abbott has succeeded in preparing a work which, though elementary in character, will adequately meet the requirements of the laboratory student and of the general practitioner who desires an intelligent familiarity with the subject. A course of a month or eight weeks in the laboratory will not make a bacteriologist. General principles, however, can be learned, and with these the general practitioner should be conversant.

Dr. Abbott wisely directs that the solutions of the anilin stains should, in general, be recent. It has not been our experience, however, that the carbolized fuchsin solution decomposes readily. On the contrary, we have no difficulty in successfully staining tubercle-bacilli with solutions several months old. We have found the method described by Gabbet as the simplest of application for staining cover-glass preparations of sputum—staining with carbolized fuchsin and decolorizing with a 25 per cent. solution of sulphuric acid containing a small proportion of methylene-blue. No alcohol enters into the process and the risks of decolorizing tubercle-bacilli are reduced to a minimum. Of experimental inoculation of animals, only the subcutaneous and intravenous methods are considered; reference to inoculation of the eye, of the serous cavities, by the digestive canal and by the respiratory tract is omitted. Illustrations of the more common and accepted pathogenic microörganisms might judiciously have been presented.

Dr. Abbott's book will prove a useful aid to those that desire a knowledge of the principles of bacteriology.

We append a letter received from Dr. Abbott that is self-explanatory:

To the Editor of THE MEDICAL NEWS,

SIR: If you can afford me the necessary space in your journal, I would like to call attention through its columns to several errors of omission that I find in my book, *The Principles of Bacteriology*, recently published by Lea Brothers & Co., of this city.

A number of methods of work as described and recommended in that book have, to the best of my knowledge, been developed in the pathological laboratory of

the Johns Hopkins University and Hospital, where I was formerly assistant, but I discover that in the haste of preparation I have failed to mention this fact in either the preface or body of the book. As some of these methods have never been described before, I think it only just that the men who originated them should have credit for their work, and I take this means of correcting what I consider a serious omission on my part.

For instance, on page 68, the method for the preparation of potatoes for cultivation in the test-tube was devised by Dr. Meade Bolton, while assistant in the above-mentioned laboratory; on page 88 the modification of Esmarch's method which consists in rolling the tube on a block of ice instead of in iced water, as Esmarch recommended, was first employed by Dr. W. D. Barker in that laboratory in 1887; the "acetic acid method" for staining the capsules surrounding certain bacteria (page 133) was suggested by Professor Welch. The suggestion in regard to movable false-bottoms for the hot-air sterilizers, with a view to economy and convenience (page 47); the employment of rosolic acid in cultures of growing bacteria as an indicator for the reaction produced by the bacteria (page 75), and the preparation of needle-points for the intra-vascular injections into the vein of the ear in rabbits (page 155), are my own.

In addition, it was in the same laboratory that Esmarch's statement that "agar-agar is not adapted for tubes which are to be called after his method" was demonstrated to be erroneous, and it was also there that the hot-water funnel was abandoned, and the ready and satisfactory method for the preparation of nutrient agar-agar, as described in my book, was developed.

It is true that laboratory methods of work are usually considered common property, and so they should be; but, as is well known, every laboratory has certain technical devices of its own, which may or may not be employed elsewhere, and which are believed by those using them to give the best results. Fundamentally, the technique given in *The Principles of Bacteriology* is that common to most bacteriological laboratories, but still there will be seen here and there through the book certain deviations from the prescribed rules, which are followed in the Baltimore laboratory, and which are believed to be of advantage in the proper performance of this work.

Most respectfully yours,

A. C. ABBOTT.

LABORATORY OF HYGIENE,
UNIVERSITY OF PENNSYLVANIA.

THE MICROSCOPE AND ITS REVELATIONS. By the late WILLIAM B. CARPENTER, C.B., M.D., LL.D., F.R.S. Seventh Edition: in which the first seven chapters have been entirely rewritten and the text throughout reconstructed, enlarged, and revised by the REV. W. H. DALLINGER, LL.D., F.R.S., etc. With twenty-one plates and eight hundred wood engravings. Philadelphia: P. Blakiston, Son & Co., 1891.

A BOOK that has passed through six editions, carries its own commendation with it. So many important changes have, within recent years, taken place in the department of microscopic research that to keep abreast of the times revision and addition became imperative. As a result of this revision and additions, the work before us is practically a new one. Great credit is due the editor for the masterly manner in which he has handled his subject and made a homogeneous whole of a vast mass of facts of diverse character. All that pertains to practical microscopy is here to be found expressed in clear and forcible language, profusely illustrated by a large number of well-executed cuts and plates.

That portion of the work that most interests the medical man—the study of normal and abnormal tissues and fluids of the human body, including the various pathogenic microörganisms and the differential modes of staining them—is deficient in some respects. We realize that a book on the microscope cannot well be also a work on histology, a work on pathology, and a work on clinical medicine; but such a book would have enhanced value if it dealt, if only in a general way, with subjects of which a knowledge essentially depends upon the employment of the microscope. Thus, there is no word of tube-casts in urine; nowhere do we find even the name trichina or actinomyces, while page upon page is devoted to the consideration of certainly less important animal and vegetable organisms.

Ten pages are devoted to schizomycetes, but we fail to find mention of the vibrio of cholera or of the spirillum of relapsing fever. Many pages are taken up with descriptions of the protozoa, but not a word is said of a malarial parasite.

Despite these rather exacting criticisms, the book remains a valuable source of reference, especially for the naturalist. It will also afford much useful information to all interested in the mechanism and employment of the microscope.

SAUNDERS'S POCKET MEDICAL FORMULARY. With an Appendix containing Posological Tables, Formulæ and Doses for Hypodermatic Medication; Poisons and Their Antidotes; Diameters of the Female Pelvis and Fetal Head; Diet List for Various Diseases; Obstetrical Table; Materials and Drugs Used in Antiseptic Surgery, etc. By WILLIAM M. POWELL, M.D. Philadelphia: W. B. Saunders, 1892.

ANY means calculated to impress the undergraduate, or the post-graduate, with the idea that medicine, and the art of therapeutics in particular, is to be learned from formulæ must be regarded as pernicious. Formularies as a part of text-books are objectionable enough, while there can be no legitimate excuse for the production of a work devoted solely to the presentation of pharmaceutical formulæ.

Therapeutics is an art, not a trade, the successful application of which depends upon an intelligent comprehension of the relation between pathological processes and the physiological actions of various medicinal agents, and not upon the mere mechanical administration of drugs, of which one is selected for the individual symptom, symptom-complex, or disease.

More harm is done by the blind employment of medicines than by their judicious withholding. In a given case more depends upon wise management than upon perfunctory prescriptions. What is now needed is a work directing the uninformed when not to give medicine.

That practitioner who cannot acquire a working knowledge of the practice of medicine without the employment of ready-made formulæ had better surrender his diploma

and take up some other mode of occupation for the successful engagement in which the broadest possible intelligence is not absolutely requisite.

A PRACTICAL RÉSUMÉ OF THE MODERN METHODS EMPLOYED IN THE TREATMENT OF CHRONIC ARTICULAR OSTITIS OF THE HIP. By CHARLES STILLMAN, M.D., Chicago. Detroit, Michigan: George S. Davis, 1891.

IT is well that the author of this work should state that it has been compiled from the writings of other orthopedic teachers, since it is made up almost entirely of extracts. It deals with the treatment of hip disease only from the narrow standpoint of a specialist, who seems to think that the sole treatment for this form of ostitis consists in the employment of some form of apparatus. A number of splints are described, but no general plan or outline of treatment is given, nor is there anything in the book to guide a practitioner even in the selection of an apparatus.

The book necessarily deals meagerly even with methods, but we think that some of the authorities named, Willard or Gibney for instance, would be very unwilling to have it considered that a splint occasionally used by them should be looked upon as "their treatment of hip disease." One of these writers, for instance, is quoted as employing this splint, when the publication from which the extract is taken distinctly states that it is chiefly used in non-inflammatory cases and in the later stages of the disease.

As a catalogue of apparatus rather than as a plan of treatment, the book is convenient; otherwise it is of little service.

NEWS ITEMS.

The Medical Association of Georgia will hold its forty-third annual session at Columbus, Ga., on April 20th, 21st, and 22d. Dr. G. W. Mulligan, of Washington, Ga., will preside. DR. DAN H. HOWELL, of Atlanta, Ga., is the Secretary.

The "Physician and Surgeon" of the January issue appears enlarged and improved. It, however, makes the mistake of printing advertisements in the context and interleaving advertisements among the reading matter.

Mütter Lectureship of the College of Physicians of Philadelphia.—The next course of ten lectures under the bequest of the late Prof. Thomas Dent Mütter, M.D., LL.D., "On some Point or Points connected with Surgical Pathology," will be delivered in the winter of 1893–94 before the College of Physicians of Philadelphia. Compensation, $600. The appointment is open to the profession at large. Applications, stating subjects of proposed lectures, must be made before October 15, 1892, to WILLIAM HUNT, M.D., Chairman of the Committee on Mütter Museum, Thirteenth and Locust Streets, Philadelphia, Pa.

The Opening Ceremonies of the Institute of Hygiene of the University of Pennsylvania were held in the Library of the University at the Opening, February 22, 1892. These consisted of: Prayer—By the Rev. Dr. George Dana Boardman. Presentation of the new building to the Provost and Trustees—Dr. S. Weir Mitchell, Chairman of the Committee on Hygiene. Acceptance on behalf of the Provost and Trustees—Provost William Pepper. Address—Dr. Benjamin Lee, Secretary of the State Board of Health. Address—Dr. John S. Billings, Director of the Institute. Address—Dr. H. P. Walcott, President of the Massachusetts State Board of Health.

The Pan-American Medical Congress in New York State.—At a meeting of the Medical Society of the State of New York, at Albany, February 5th, a committee was appointed to coöperate in promoting the interests of the Pan-American Medical Congress. The committee consisted of Drs. A. Walter Suiter, A. Vander Veer, James D. Spenser, Seneca D. Powell, W. W. Potter, D. B. St. John Roosa, and John O. Roe.

OBSCURE FORMS OF GOUT.[1]

BY CHARLES W. DULLES, M.D.,
PHYSICIAN TO THE RUSH HOSPITAL, PHILADELPHIA.

SOME years ago a friend of mine, a physician, while travelling in Europe, was the subject of an obscure sense of ailing. He was not absolutely ill, he thought, but was not quite well, and had a feeling of depression for which he could not account. Being in London, he made up his mind to consult Sir William Jenner. After a visit, at which Sir William subjected him to a careful physical examination, he was surprised upon being told that his trouble was gout. His surprise finding some expression in his countenance, Sir William said to him: "You do not believe me, but you will find I am right. You Americans know little about gout, because you do not see much of it, and what you see you do not recognize." Within a few days my friend awoke one morning with a most obvious attack of gout in one of his feet; and his respect for gout and for Jenner's diagnostic ability was considerably increased.

This story is so closely in the line of some recent observations of my own that I have chosen it to introduce a brief presentation of them and the reflections to which they have given rise in my mind.

Gout is a disease that, in the last few centuries, has been studied with great thoroughness by the English, the French, and the Germans, and it is probable that the earlier American physicians, following the teachings of older and contemporary English writers, and dealing with patients of habits very similar to those of their English ancestors, were alert to detect its presence. But I have the impression that Sir William Jenner did not exaggerate much when he expressed so strongly the idea that in our day gout is not taken into account by American physicians as it ought to be, while an indication as to the degree of attention it has received from the American authors of medical works may be found in the fact that the Index Catalogue of the Surgeon-General's Library at Washington contains nearly twelve columns of titles of books on gout, and among them I find only three books—and these not imposing—by American writers.

[1] Read before the College of Physicians, March 2, 1892.

Within the past few months three cases of gout—among others—have come under my care, which strikingly illustrate the importance of recognizing forms of gout that depart from the picture usually regarded as typical. These cases have been so instructive to me that I think it may be of service to describe them.

The first of the cases was that of a gentleman of means, but actively engaged in a business that required much thought and involved serious responsibilities. He is about fifty-five years old, of full habit, and "a good liver," but free from all forms of intemperance. Near the end of last winter his son brought him to my office in a condition that is hard to describe, but one that each of us has probably often seen. The man did not present any marked signs of disease, but he was pitiably unnerved and broken down. His appetite was poor, his sleep disturbed, his bowels somewhat irregular. He seemed so much to need mental rest that I suggested that he go away to Florida. I wished to examine his urine, but he slipped away to a health resort in North Carolina before I had an opportunity to do so. He came back in a few days feeling much better, and I did not hear from him for some time. Several months later, I was asked to see him by his regular family physician, and found that after a short spell of feeling out of sorts, he had fallen one day on the staircase of his house in what was called a "faint." On inquiry I found that in the "faint" the patient had continuously opened and closed one hand. In other words his attack was not one of syncope, but a convulsion. His regular attendant and I agreed that we must study his urine, and on doing so I found in it a large number of crystals of uric acid. As he was at that time about to go with his family to Europe, I warned him in regard to the dangers of the gouty diathesis, and advised him how to avoid them as far as possible. A few weeks later he wrote me from Paris: "You are a good prophet; I have just had a pronounced attack of gout in the foot." Since then he has returned to his home, and had several more attacks of equally typical character.

The second case was that of a lady living in the quiet of an admirable family. Nearly two years ago, she had an attack of "grip" when the epidemic was most severe in this country. After that she was never quite as well as she had been before. About six months ago she began to suffer with pains of a neuralgic character, which were especially severe in the thighs and in the lower part of the back, and which appeared also in the chest-wall and elsewhere. Some of these closely resembled the pains of sciatica. She was not under my care; but once or twice in the

absence of her regular physician, I was called to see her; once when I gave her a subcutaneous injection of one-quarter of a grain of morphine, I was much impressed with the fact that this dose of morphine quieted her and kept her asleep or sleepy for fully thirty-six hours. Some time after this, while away from home, she suddenly developed symptoms of advanced disease of the kidneys, and was brought home, with waxy complexion, edema of the face and legs, oppressed breathing and a general appearance of the phenomena of contracted kidneys, and died in twenty-four hours. This patient's knuckles were knobbed, and I have no doubt, from a long acquaintance with her, from observations made on occasional visits, and from the manner of her death—for ten hours preceding which I had her under almost constant observation—that she died of contracted kidney due to gout.

A third case of gout that did not present the most conspicuous manifestations of the disease was that of a physician, about forty-five years old, a man of means and not in practice. Last June he sent for me, and when I came, he said: "I am afraid to see you; because I think that I have an aneurism of the aorta, and I fear you will confirm my opinion." He then described symptoms, some of which are found in cases of aneurism of the aorta, and submitted to a thorough physical examination. I found no evidence of aneurism whatever, and told him so, when he naturally asked me how I accounted for his symptoms. In preparing an answer to this query, I inquired pretty fully into his history and examined his urine. The former gave distinct points consistent with a theory of gout, and the urine showed an abundance of crystals of uric acid and oxalate of lime, some kidney epithelium, and no casts, albumin, or sugar.

I then told my friend that I believed his symptoms were due to gout, and advised a regimen in accordance with that theory, and the use of a natural mineral water which I have found advantageous in similar cases. In a few days he felt better; in a few weeks he felt well; and to-day he is apparently in perfect health. A year ago he was unable to enjoy anything; to-day he is full of spirit and enjoys everything. A year ago he could not walk a hundred yards on a slight ascent, without dyspnea and precordial distress; now he walks miles with ease and pleasure.

It would be a work of supererogation for me to dwell upon the symptoms and course of frank gout, for these are familiar to every practitioner of experience, especially in our older cities. In throwing off the British yoke the American colonists secured no independence from the diseases of their British progenitors; and the tendencies that our forefathers inherited, though they may have been kept in abeyance while the nation was passing through the arduous and heroic epochs of its early history, seem to be finding more pronounced expression, now that the number of persons living in comparative ease or actual luxury is increasing. As it was in Greece and Rome, so it has been in England and on the continent of Europe, and so it is likely to be in America. Abernethy's advice to "live on a shilling a day, and earn it," indicates a road to health that is constantly being deserted by Americans, and as a result, the diseases of over-feeding and inadequate muscular exercise must become more conspicuous among us. For this reason gout is likely to secure more and more victims in this country, and consequently it is well that American practitioners should be prepared to recognize not only its striking forms, but also those that are irregular or obscure.

In his classical work on *Gout and Rheumatic Gout*, Garrod says that, while gout in its most marked and typical manifestations is exceedingly prevalent in England, "in its lurking and undeveloped forms it is probably still more so, and exercises a considerable influence over the character and progress of other disorders." From this, it is a natural step for him to emphasize the importance of properly distinguishing gout from other diseases, of recognizing it when it is present, and at the same time avoiding the error of attributing to gout what are really manifestations of other disorders. Everyone who becomes especially interested in a particular disease is in some danger of falling into such an error, and the more likely to do so as the idea of anomalous forms of that disease takes possession of his mind.

In determining the diagnosis of gout we must study the history of the case—the hereditary tendency of the patient, the existence of predisposing or exciting causes, and the symptoms. In retrocedent gout—that is, the development of visceral disorders or lesions upon the disappearance of gout from the joints—the case is simple, although Garrod aptly quotes a remark by Watson that "so-called *gout* in the stomach has sometimes turned out to be *pork* in the stomach." There is undoubtedly a form of dyspepsia in persons predisposed by heredity to gout that may justly be attributed to this disease; and this form of dyspepsia is sometimes relieved upon the appearance of gout in a joint, while treatment suitable to gout proves curative of it.

Gout of the heart is often associated with gouty dyspepsia; but Garrod speaks of cases in which palpitation, and irregularity of rhythm have been produced by the state of the blood. Dyce Duckworth, in his elaborate work on *Gout*, emphasizes the importance of what may be called minor symptoms of disturbed action of the heart, such as giddiness and dimness of vision, in gout. A case of my own has impressed me with a similar conviction. I am myself inclined to believe that certain forms of angina pectoris are dependent upon the gouty dyscrasia. I have seen three cases in which long-continued disturbance of the functional action of the heart

seemed to me to be altogether dependent upon gout, to which the patients were liable by heredity or by their habits, and of which they presented other manifestations. This is a subject that I think deserves very careful investigation, so that we may ascertain just how far we may look to the gouty habit to account for heart symptoms that are not otherwise easy of explanation.

The effect of gout in producing cough, dyspnea, and even asthma, is recognized by almost all authors, but there is danger, I think, of attributing such disorders unjustly to gout, with which they may be merely coincident. At the same time it is proper to recognize that, if not directly induced by gout, the conditions named may be exaggerated or made less amenable to ordinary methods of treatment by reason of the gouty dyscrasia. Examples of this tendency have certainly occurred in my practice.

The kidneys are probably the organs that are most likely to undergo serious alterations in consequence of unsuspected gout, and a recognition of this fact is of the utmost importance. Draper, in his admirable article on gout in Pepper's *System of Medicine*, speaks forcibly of the insidious character of gouty nephritis, and states that gout of the kidney is the most common cause of death in this disease. The observations of other writers on gout are in accord with this statement, and it can hardly be dwelt upon too strongly in studying the possibilities of gout. In one of the cases briefly described I believe that a careful study of the history of the patient, and a due consideration of the possibilities of gout, would have prevented a very erroneous prognosis on the part of one physician who treated her, and perhaps have led to a more appropriate line of treatment.

In this particular case a consultant of large experience was quoted to me as treating with apparent unconcern the state of the kidneys, because the quantity of albumin found in the urine was small!

Such a statement suggests either an error in the account of what was said, or a serious misapprehension of the significance of the presence of small quantities of albumin in the urine. On the other hand, it is possible that large quantities of albumin may be found in the urine during comparatively slight attacks of gout. Very recently I had under my care a young lady who was suffering with an attack of podagra, very well defined but of moderate severity, whose urine contained enough albumin to make, with underlying nitric acid, a coagulum one-third of an inch thick. This patient presented no other symptom of kidney disease—her urine was repeatedly and thoroughly examined—and she made a good recovery from her attack of gout.

Temporary glycosuria is another evidence of faulty nutrition or disordered excretion which is found in some cases of gout. Dyce Duckworth points out the danger of mistaking this phenomenon for diabetes mellitus, and especially of communicating this erroneous belief to the patient or his friends.

The influence of gout upon the skin has been especially emphasized by certain French observers. Draper cites Bazin (*Affections génériques de la Peau*, Paris, 1862) as describing functional derangements of the skin dependent upon gout, such as excessive perspiration, seborrhea, alopecia, pruritus, urticaria, and erythema. Eczema is a well-recognized manifestation of the gouty diathesis, and Draper calls attention to the frequency of acne in persons predisposed by heredity to gout. Garrod, in 1881, stated that he regarded eczema as the special skin-lesion of gouty subjects. I have noticed a peculiar fetid, or rather a sour perspiration in a few persons belonging to gouty families, some of whom in time developed frank attacks of gout. As connected with the skin, it is interesting to note that Dyce Duckworth speaks of spontaneous loosening and falling out of the teeth as a manifestation of gout.

One of the most important manifestations of obscure gout is neuralgia. There is hardly a writer on gout who fails to call attention to this feature of the disease, and yet I believe it is by no means properly appreciated. The neuralgia of gout may affect any region that an ordinary neuralgia may invade, and may easily be misinterpreted. This is especially true of the sciatic region; so that what is only a manifestation of gout may be called sciatica. One feature of such cases that may be noted is the fact that the neuralgia of gout appears in various places at the same or at different times. The ham, the calves of the legs, the loin, the side of the chest, the arm, and the area of distribution of the fifth pair of nerves, may be the seat of severe and even agonizing pain; and this very shifting of location ought to warn the physician to carefully consider the possibility that gout is the cause of the phenomena.

Other manifestations of gout in the nervous system are vertigo, loss of consciousness, and even epileptiform convulsions. These are rarely of a very pronounced character, but Garrod mentions one case under his observation, and one of the cases I have described presented this group of symptoms. The relation of gout to this and other forms of cerebral disturbance is not yet clearly defined, and it would probably be useful for men of large experience to study their cases with especial reference to this relation. In my practice I have observed that in some subjects gout has a peculiarly depressing influence, so that they are easily disheartened, and lack vigor of will. Laycock has called attention to the influence of gout in producing hysteria, and many

authors connect it with hypochondriasis. Dyce Duckworth has been so impressed with the nervous features of gout that he defends the hypothesis that gout is a neurosis. He also speaks of the occurrence in gout of violent pains in the muscles—as, for example, cramps in the legs.

These remarks do not by any means cover all the manifestations of gout that may be misunderstood, but which, if duly considered, may lead to its diagnosis when what are universally recognized as its typical symptoms are absent; but it is hoped that they may serve to attract attention to, and perhaps also throw a little light on, a subject that is of some consequence in our study and treatment of disease.

As already stated, I have the impression that in this country gout often escapes diagnosis, and that it would be better for our patients if we were on the alert to detect its less familiar features. We do not want to deceive ourselves by a too ready disposition to find gout where it is not actually present; but, to keep in mind that gout may be the cause of a great variety of symptoms, and to know what some of these symptoms are, may at times make our diagnosis much more satisfactory and our treatment much more successful than they otherwise would be.

DIPHTHERIA TREATED BY THE EARLY LOCAL USE OF GERMICIDES.[1]

BY ROBERT REYBURN, A.M., M.D.,
PROFESSOR OF PHYSIOLOGY AND CLINICAL SURGERY, MEDICAL DEPARTMENT HOWARD UNIVERSITY, WASHINGTON, D. C.

Diphtheria is admitted to be a disease caused by a microscopic germ or bacillus commonly known as the Löffler bacillus, or more often called the Klebs-Löffler bacillus. The only point now in dispute is as to whether other poisonous microörganisms (saprophytes), as well as the Löffler bacillus, have the power to cause diphtheria.

The course and termination of a case of true diphtheria in man, is typically characteristic of the invasion of a living organism by a poisonous germ. There is first the period of incubation, sometimes marvellously short, in some cases extending over a period of a few days, or even hours; this is, of course, the period when the bacillus is germinating and preparing to do its deadly work. Then generally follow the initial chill and fever—temperature ranging from 100° to 103½°, but without the defervescence that follows the chill of malarial fever. Coincidently with or immediately following the chill, will generally be found, on some part of the tonsils, uvula, or pharynx, the characteristic yellowish or grayish-white exudation that has so often struck terror to our hearts. Then follows the steadily advancing growth of the false membrane, extending backward and downward upon the walls of the posterior part of the pharynx, even to the larynx and trachea, or upward and backward to the posterior nares. As the exudation increases, there arises the enlargement of the submaxillary glands, and septic fever produced by the absorption of the poisonous ptomaïnes generated by the bacilli and absorbed into the blood. If unchecked, these symptoms continue until death speedily comes, either from strangulation, or what is much more frequently the case, from true septic fever, closely analogous or identical with that produced by the absorption into the system of the putrid material found in dissection wounds, hospital gangrene, or pyemia.

The plan of treatment I propose is not the application of new and untried remedies. On the contrary, it is simply the application of our old and well-known methods of treatment, in consonance with the laws that hinder the growth and destroy the bacterial germs that are the cause of diphtheria.

What germicide, then, or agent having power to destroy bacterial life, can we most readily use? Corrosive sublimate is the one almost universally used, and is the one that I have employed. I use it in spray and in a stronger solution than usually employed, viz.: one grain, with five grains of tartaric acid, in a little over a fluidounce of distilled water, 1 : 500; this is liberally sprayed at least once an hour for the first twenty-four or forty-eight hours. When the exudation disappears, I dilute the bichloride solution to 1 : 1000 or even 1 : 2000. After I am called to a case of diphtheria, alternately with this I apply every hour to the fauces and tonsils, with a camel's-hair throat-brush, a solution of twenty grains of chloral hydrate in a fluidounce of glycerin. These applications are to be made continuously for a period of from twenty-four to forty-eight hours, according to the gravity of the case, until the exudation begins to soften and peel off; the applications are not then made so frequently. The use of this is twofold; in the first place the continued use of the glycerin, aided by the powerful antiseptic action of the chloral hydrate, softens the false membrane and leaves a clean surface on which the bichloride of mercury can act. At the same time I direct either that water be kept boiling in the room, to saturate the air with moisture, or that lime be slaked in the room.

As to medical treatment, I give in solution from two to four grains of quinine every three hours, until from sixteen to thirty-two grains have been given, the dose being proportioned according to age. Then I commence and give the tincture of the chloride of iron in large doses every three hours alternately with the quinine. This treatment, continued

[1] Read before Medical Society, Washington, D. C., December 2, 1891.

for from forty-eight to seventy-two hours, has in my hands met with almost universal success.

The objection may be made to this treatment, that it is very laborious to the person who is nursing the child, and this is true.

When called, I say frankly to the parents that, in my opinion, the life of the child will depend upon sacrificing every other consideration, and for two or three days upon continuous and exclusive devotion to the care of the child.

About two years ago, I attended a child six years of age, attacked with diphtheria in its most malignant form. Day after day I watched the false membrane encroaching more and more upon the back part of the throat and soft palate. Then came enormous swellings of the submaxillary and parotid glands, which turned a livid purplish color. With this a condition of true septic fever developed, from the absorption of the poisonous ptomaïnes generated by the bacilli. All treatment seemed unavailing, and when I left the house after the child's death, I felt so completely disheartened with the failure of my attempt to save the child's life that I felt almost like abandoning the practice of medicine forever. Studying over this case and many others of like character that I had met with during the past years of my practice, I began to feel certain that my want of success was due to a lack of energy during the early stages of the disease, and that a more active treatment directed to stamping out the disease when it was just beginning its ravages would be the proper course to pursue.

These are the principles that have guided me in the treatment of the cases that form the basis of this paper. The number of cases was only fifteen, yet the result has been so uniformly good (as they have all recovered) that I now go to a case of diphtheria with a confidence of a successful result that I had never felt before.

I need not go into the detail of the histories of the cases, but will only give such points as may be interesting. The first five cases occurred in one family over a year ago, and after a prolonged struggle they all recovered. The next two cases occurred in October of this year in one family; one child of nine years brought the disease from the country, where she had been staying during the summer. She came home on Saturday and I did not see her until the following Tuesday. Her attack was quite severe, involving the fauces and posterior nares. She had infected her sister before I saw her. Case No. 8, in another family, was interesting from the fact of a relapse occurring on the ninth day from imprudent exposure. The diphtheritic exudation returned on the fauces, after having completely disappeared for several days; in this case I applied a strong solution of nitrate of silver to the patch of diphtheritic exudation membrane, with excellent results. Case No. 9 was a girl, aged thirteen years, with quite extensive patches of membrane covering fauces, uvula, and tonsils. The temperature was 102° on the first day, and falling in three days to 100½° (in morning), with a gradual abatement of all the symptoms. Case No. 10 was a girl, aged fifteen years. There was complete recovery in three weeks. Cases No. 11, 12, 13, 14 and 15 all occurred in one family. The two boys were first attacked, one fifteen years of age and the other five; then the two girls, aged ten and twelve years, respectively. Then the mother was attacked; and finally the infant child, eight months old, took the disease. In the case of the infant, after the exudation had disappeared from the throat, the disease assumed the form of a bronchial catarrh, and the case seemed well-nigh hopeless. The energetic use of stimulants, hot mustard-poultices, and the internal administration of carbonate of ammonium and spirits of turpentine in large doses saved the child's life.

As to other local remedies, I have used solution peroxide of hydrogen largely. It is an admirable deodorizer and disinfectant, but I have not found it as good a local application in diphtheria as the bichloride solution. Listerine, diluted with from one to four parts of water, is also an excellent application, used as a spray or gargle, when the bichloride seems to irritate, and for a time may require to be stopped. In none of my cases has the bichloride solution caused any symptoms of mercurial poisoning. Should symptoms arise, of course its use should be temporarily stopped, continuing, however, the swabbing of the throat with the chloral and glycerin solution, and substituting the diluted solution of peroxide of hydrogen (one part to four parts of water), used with an atomizer, in place of the bichloride of mercury solution.

As regards prophylaxis or prevention of diphtheria, granting that diphtheria is due to a poisonous germ it would seem to be proper to use weak germicides in the case of all persons who have been exposed to the contagion of the disease, even though they may not by any external symptoms show that they are infected. I would earnestly recommend, therefore, that the bichloride of mercury solution 1 : 2000 or even 1 : 4000, be used either as a spray or gargle five or six times a day by all persons residing in the house in which a patient is sick with diphtheria.

If the attending physician objects to this, let him use in the same way the diluted solution of peroxide of hydrogen or the solution of chloral hydrate in glycerin, twenty grains to the ounce of glycerin—this is to be diluted with three parts of water when used as a spray; or Listerine, diluted with from one to four parts of water, may be employed.

A careful and thorough examination of the throats

and mouths of the members of the family residing in the house in which a case of diphtheria exists should be occasionally made by the attending physician, in order that the disease may be detected in its early and curable condition.

After a somewhat lengthy experience of the effects of alcohol, I must most earnestly protest against the use of alcoholic liquids, especially when given in large doses. Alcoholic liquids are most valuable and indispensable remedies, but they should be given in small doses and repeated at regular and stated intervals. I rarely give more than one or two teaspoonfuls of good whiskey or brandy, well diluted and sweetened, every three, four, or six hours, according to the age and condition of the child. Alcohol, when given in liberal doses, it should be remembered, is not a stimulant, but on the contrary is a powerful narcotic and depressant. The action of alcohol upon the heart is like the use of a spur to a jaded horse, and its continued use in too large quantities will increase instead of diminishing the irregularity and feebleness of the circulation. I have seen cases of heart-failure and death after diphtheria which I feel convinced were hastened in their progress, if not entirely caused, by the injudicious use of alcoholic stimulants in too large and frequently repeated doses.

During the convalescence from diphtheria, small doses of whiskey or brandy should be given three times a day, after meals, to obviate the tendency to heart-failure that is apt to occur, and that sometimes happens even after convalescence has been thoroughly established. It is, of course, to be understood that during the treatment of the cases referred to in this paper care was given to keep up the strength of the patients by the liberal use of liquid and easily digested food.

FRACTURE OF THE BASE OF THE SKULL.[1]

BY LEOPOLD SCHILLER, M.D.,
OF MILWAUKEE, WIS.

IT has been a generally accepted belief that a fracture at the base of the skull is almost necessarily fatal. Still, there is quite a number of cases on record in which the diagnosis of fracture of the base was made and the patient recovered. Wagner even ventured to state that when a patient with fracture at the base survives without untoward symptoms, it is pretty sure that he will recover. He cites twenty-three cases, all of which recovered—that is to say, that did not die within forty-eight hours after the accident. This has induced many surgeons to doubt the correctness of diagnosis in many of these cases. But there has been a sufficient number of autopsies of such cases made to antagonize and refute the doubt. As shown by a large number of cases, the most frequent seat of fracture of the base is in the middle fossa, and the majority were in a transverse direction through the pyramidal petrous portion of the temporal bone. These fractures also have a tendency to branch forward along the side of either cavernous sinus into the sphenoidal fissure. This will explain certain symptoms of paralysis, as that of the third nerve, thus producing dilatation of the pupil and strabismus. Those fractures of the base are produced by a transmission of the impulse from the vertex or lateral portion of the calvarium. There is still another form of fracture, called fracture by *contre-coup*, the existence of which is doubted by some of the best authorities. These may be considered fractures by direct violence, in so far as the force is brought to bear directly on the point of impact, as when a man falls upon his feet in a rigid manner, and the base of the skull is broken through the foramen magnum, while the atlas may be dislocated into the cranial cavity; or, when falling on the face, the petrous portion is fractured, while perhaps one or the other head of the lower jaw is driven through the articular process, just as the head of a hammer may be driven into the handle by striking the handle against some solid object. These are the severest forms of fracture, and, of necessity, fatal. The fractures by blows from above, arteriorly, posteriorly or from either side, are as a rule mere fissures, and not comminuted fractures.

The immediate danger from a fracture at the base is that of injury to the brain-substance proper, its coverings, the bloodvessels, both cerebral and meningeal. The carotid artery is rarely, if ever, injured. If the injury to cerebral substance is slight, and no large bloodvessels are injured, the symptoms of concussion will rapidly disappear, and there will not be marked symptoms of compression, as the hemorrhage that would produce these is not sufficient to interfere with the functions of the brain.

After recovering from the immediate effects of the injury, the question of secondary inflammatory processes arises, provided there has been a dissolution of continuity in the vault of the pharynx, the roof of the nasal fossa, or the auditory meatus and tympanic cavity. However, with ordinary antiseptic precautions these dangers are reduced to a minimum. The patient, however, may succumb to an osteomyelitis, suppurative meningitis, abscess of the brain, or thrombosis. The healing of the bone takes place by the least possible amount of callus cementing the fissure.

The diagnosis of a fracture of the base is made from certain symptoms due to the communication of the fracture with one or more of the fossæ of the

[1] Read before the Milwaukee Medical Society, November 10, 1891.

skull. One or more of these symptoms will be present in all of the cases. If the fracture extends into the posterior or occipital fossa there will be ecchymosis into the mastoid region and in the neck; if in the anterior or middle fossa there will, as a rule, be ecchymosis of the orbits. These ecchymoses come on in a few days after the injury has taken place, and are quite diagnostic. These symptoms may be absent, however.

Hemorrhage may take place from the nose, the ears, and the mouth, and if blood has been swallowed there may be vomiting of blood, more or less modified by the gastric juice. The flow of blood from the ears does not necessarily indicate a fracture of the petrous portion, since a simple rupture of the tympanic membrane may give rise to a flow of blood from the external meatus. If, however, the flow continues for some time, one may be pretty sure that there is a fissure of the bone. Another symptom sometimes shows itself, and is of grave significance—the flowing of a limpid fluid from the external meatus, usually on one side. It is at first mixed with blood, but later assumes a straw-color appearance. It is generally agreed upon that this fluid is derived from the subarachnoid space, and is the cerebro-spinal or subarachnoid fluid. It sometimes appears in large quantities. Many of the cases in which this symptom appears are fatal, though a large number of them also do recover. If they recover, the flow ceases in six or seven days. This symptom may be present without any rupture of the tympanic membrane, as also may the flow of pure blood.

Besides injury to the brain-substance itself, certain nerves are very often partly or completely torn, or there may be neuritis with effusion, resulting in compression of the nerves, with paralysis of the muscles supplied. Those most commonly injured are the facial and acoustic, which are directly in the line of the most frequent seat of fracture, the third nerve or motor oculi, and the sixth or abducens—in fact, any nerve or group of nerves may be implicated.

I have already said that fractures at the base are not as fatal as was formerly supposed, though some doubt the correctness of diagnosis in those cases that recover rapidly. It is a fact that though they do recover, there are defects, sometimes imbecility and other cerebral symptoms, as epilepsy, etc., or defects of innervation, which may be permanent. Very often, however, the nerves recover their functions almost or quite completely. As to treatment, there is only one indication that can be fulfilled, and that is antisepsis. Of course, absolute rest is necessary. If there has been bleeding from the nose this cavity must be frequently syringed with a non-irritating antiseptic solution. Both ears and nose may be syringed with a concentrated boric-acid solution, and boric-acid powder should be blown into the auditory canals. Mild diet, and perhaps an ice-bag to the head, are advisable; also, if constipation exists, a saline purge.

I present herewith an illustrative case:

F. B., a laborer, aged thirty-three, on the 20th of June, 1891, while assisting in lowering by means of a rope an iron column, weighing about 1000 pounds, was struck above the right ear by a swinging column and thrown on his head against a four-by-four beam. He became unconscious, and, as he said when he regained consciousness after about twenty minutes, he did not know what had happened to him, having in the meanwhile been transferred to the Emergency Hospital, a distance of four blocks from the place of accident. The external evidences of injury were a scalp wound, about three inches in length, about two and a half inches above the right external auditory meatus, extending antero-posteriorly, and exposing the periosteum. The left ear was severely bruised. There was bleeding from both ears, from the nose and mouth. He also vomited blood after regaining complete consciousness. There was immediately noticed a paralysis of both sides of the face, even of the fauces. There was bilateral lagophthalmus and a convergent squint of the left eye, the pupil of which eye was also larger than that of the right, and sluggish in action.

The temporal wound was sewed up with catgut sutures, and dressed antiseptically. The nose and ears were washed with a boric-acid solution, and iodoform was blown into the ears. The man was then taken home. I called on him on the morning of June 21st. The hemorrhage still continued. He spat blood; blood came when he blew his nose slightly; and blood flowed from both ears. I again washed his nose and ears with a boric-acid solution, and blew the acid powder into his ears instead of the iodoform. He complained of severe headache and pain in the eyes, also of amblyopia of the left eye. I ordered an ice-bag to his head, and had the room darkened; I also had his nose syringed a number of times during the day. The headache continued for about five or six days, gradually diminishing until it disappeared, leaving, however, a sensation of dizziness that lasted several weeks. There was no elevation of temperature at any time. The pulse was at first somewhat retarded—60 per minute; after a few days it became from 72 to 76, and stayed there. There had been vomiting immediately after the accident, but only the single attack. The hemorrhage gradually diminished and ceased in about a week. After two weeks the syringing was discontinued, The temporal wound had completely healed by first intention, and the patient was able to sit up. The right side of the face was beginning to regain its mobility, and after three weeks the patient was able to close the right eye, and wrinkle the forehead on the right side. The left side showed no signs of improvement. I began treating it with mild currents of galvanic electricity for five minutes every other day, and although the muscles reacted well to the current, though sluggishly, there was no perceptible change after four weeks of treatment, so I discontinued it, not expecting to see that side

recover its functions. About the beginning of September the patient returned to me with an abrasion of the left cornea and an iritis, for which I sent him to Dr. Bach. I was surprised to find that he had regained considerable of the motility of the left side, and that the strabismus was disappearing. He then complained of a salty taste in the mouth, and this sensation still continues. On testing, the sense of taste is diminished most markedly on the left side, as are also the sensations of touch and pain in the tongue. The function of the seventh nerve is now almost completely, if not completely, restored; the strabismus and concomitant diplopia are gone. The man, however, complains of a weakness of vision, also of a certain deafness and ringing in the head.

Dr. Bach recently made an examination of the eyes and ears, and found the tympanic membranes intact, though there are several spots of calcareous deposit, perhaps due to extravasations at the time of injury. Hearing $\frac{5}{6}$ on both sides.

There is a general congestion of the retina, and the bloodvessels are tortuous. I do not know whether this is of both eyes or of the left only. The vision of the left eye is $\frac{1}{3}$, and of the right eye $\frac{2}{3}$. The eyes are very irritable. The lids are in a catarrhal condition, the conjunctivæ bulbi congested.

The patient says he does not feel as well now as he did a few weeks ago. The dizziness and ringing in the ears trouble him, as does also the paresthesia of the tongue.

CAUSES OF THE DIMINISHED PREVALENCE OF TYPHOID FEVER IN DENVER.[1]

BY T. E. TAYLOR, B.A., M.D.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND CLINICAL MIDWIFERY IN GROSS MEDICAL COLLEGE, DENVER, COL.

WHEN a disease that for several years has been widely prevalent, causing many deaths, becomes much less frequent, we naturally are led to employ some of the leisure thus afforded in investigating the causes of the change, with a view to throwing some light on the conditions favorable to the development of the specific germ of such a disease. That typhoid is less prevalent in Denver this year than in previous years is the universal testimony of the profession and is clearly shown by the records of the Arapahoe County Hospital. In 1888, up to August 15th, 62 cases were admitted. In 1889, up to the same date, 66 were admitted. In 1890, 69 were admitted, while in 1891 only 35 were admitted. The same conclusion is reached by investigating the mortality reports of the Board of Health.

To ascertain the cause of this condition, it is necessary to note the particulars in which this season has differed from others, and then we shall be in a better position to estimate the influence of each of these variations upon the development of the specific bacillus.

The average temperature during the summer of 1891 was much lower than usual, the mean temperature during June, July, and August being only 63.4°, 68.9°, and 69.7° respectively, against 67.6°, 74.8°, and 69°, for 1890, and 62.4°, 72°, and 72.8° for 1889; the total deficiency in temperature from January 1 to August 3, 1891, being 699°.

The most noticeable peculiarity of this season was the unusual rainfall, the precipitation during the year up to and including August having been vastly beyond the average, the total excess in precipitation for the eight months from January 1st to August 31st amounting to 6.58 inches, or about 50 per cent.

Both coolness and moisture doubtless retarded the development of the germs: the former, as warmth is favorable to their growth; the latter, as the abundant rains washed away much of the accumulations of filth of all sorts that furnishes the most favorable soil for their development. Moisture probably has a further effect by raising the height of the ground-water, which this year has been much nearer the surface than usual, as is shown by the general testimony of people having wells that the water in them is much deeper than usual, and also from the fact that in north and west Denver the cellars have, in many cases, been partially filled with water.

Pettenkoffer believed that the distance of the ground-water from the surface was the most important factor in the causation of typhoid, as shown by some observations made by himself and Buhl at Munich, and repeatedly since then has it been observed that when the ground-water was far from the surface, typhoid was prevalent, and *vice versa*. No thoroughly satisfactory explanation of this fact has yet been brought forward. Baker, secretary of the Michigan State Board of Health, supposes that the contents of privy-vaults, as they soak through the soil, spread laterally as they descend, the soil so saturated forming a cone, with its apex at the surface; thus the deeper the ground-water the larger the base of this cone and the greater the number of wells that it would reach and contaminate. Whether or not this supposition can satisfactorily account for the diminished prevalence of the typhoid is doubtful. A rise of from two to six feet in the level of the ground-water would not contract the base of the cone of saturated soil to an equal extent, but even if it did, the influence of such a limited contraction could not be great, even in localities where the drinking-water is obtained from wells, as comparatively few wells would be included within this space, while it utterly fails in cases in which the water-supply is rived from streams or lakes at a distance.

The cause of present greater healthfulness, how-

[1] Read before the Arapahoe County Medical Society.

ever, must not be sought alone in these climatic peculiarities. The Department of Public Health has been much more active and efficient than heretofore, securing a more prompt removal of garbage, emptying and disinfection of cesspools, putting in thousands of sewer connections, and condemning a large number of wells. The value of these various factors can only be guessed at, but must have been considerable. This is indicated by the fact that the unsewered district, containing about two-fifths of the population, furnished during July seventy-nine deaths from all causes, while in the sewered districts, containing three-fifths of the population, there were only sixty-four deaths from all causes. During August the unsewered two-fifths furnished seventy-nine fatal cases from all causes, while the sewered three-fifths only furnished fifty-seven. I was unable to ascertain what part of these deaths was due to typhoid, but probably the proportion of deaths from typhoid to deaths from all causes was larger in the unsewered than in the sewered districts.

Also considered by wards, we find that the third, seventh, eighth, and ninth wards, which contain most of the unsewered parts of the city, furnished in July eighty-eight and in August one hundred and eleven cases, while the remaining five wards, which are sewered, furnished in July only fifty-five and in August only forty-five cases. In these districts, also, much of the water is obtained from wells, the water of which has been analyzed in many cases, and almost invariably found unfit for use.

Another possible cause may be found in the changed water-supply. Until 1891 the water was supplied by the Denver Water Company, being obtained from underground reservoirs below the bed of the Platte River, the water filtering through the sandy bottom into them. These reservoirs are situated just above the city and below the villages of Fort Logan and Littleton, the sewers of which empty into the river and contaminate the water, as the germs so introduced must be but imperfectly, if at all, removed by the filtration through a few feet of sand. This summer most of the principal streets have had the mains of the new Citizens' Water Company as well as those of the old company, and many of the houses have changed their water connections to the mains of the new company, the water of which is brought from the mountains in underground pipes, removed from any opportunity of contamination in transit. What influence, if any, this change has had upon the prevalence of typhoid, can only be conjectured. To prove anything, it would be necessary to ascertain what relation the number of cases of typhoid in houses supplied by the new company bears to the total number of houses supplied by the company, and also what relation the number of cases in houses supplied by the old company bears to the total number of houses supplied by this company; when, by comparing these ratios it could be seen whether or not the new water-supply had diminished the prevalence of typhoid. This, however, is impracticable.

Great as is the credit due our present Health Department, I think that only a part of the improvement in the public health is due to the improved sanitary condition brought about by them, as we find a similar improvement in the surrounding cities and villages, which, of course, share with us the unusual climatic conditions, while their sanitary condition is unchanged. If our next summer shall be hot and dry, while the sanitary condition continues to improve, we shall be in much better position to estimate the value of each of these factors than we now are.

LEPROSY.

BY A. LAURENT, ESQ.,
OF NEW YORK.

AN article published in a leading paper some time ago concerning leprosy in Jamaica, West Indies, created quite a sensation in New York, as if the fact were a new discovery; but it must be remembered that lepers may be found in Norway, in Ireland, in Central and South America, in the Antilles, in Oceanica, in Africa, and in Asia. In Europe nowadays the disease is absolutely under control, while elsewhere, beyond any doubt, it is spreading. Absolute segregation is generally considered as the best remedy, but governments experience great difficulties in enforcing the law. These difficulties are of various kinds. In extensive countries it is practically impossible to reach all the lepers. Then the question, Who is a leper? is sometimes very difficult to solve. The disease may not develop before eight, ten, fifteen, or twenty years—in case of women, often not before marriage—and the very limited knowledge concerning the disease professed by many physicians makes any step dangerous to take. Segregation also has many adversaries who, on the ground of humanitarian feelings, and looking only at one side of the question, advocate the right of man to individual liberty. Finally, and this is perhaps the point most important of all, leprosy attacks not only the poor, but many wealthy men and families suffer; and through influences manifesting themselves in various ways the latter manage to prevent any law or bill from passing, or, if enacted, to avoid its effects. That is the reason why all of the work done by several commissions appointed in England during the past fifteen years has proved sterile. Segregation, again, must be strict, general, and absolute; otherwise it is useless. In all of the reports

made on the subject, the spread of leprosy is intimately connected with vaccination with humanized virus, and this seems to explain how in Europe, where, outside of better hygienic conditions, every possible care is taken by physicians in vaccinating, the disease is disappearing, while just the reverse is taking place in other parts of the world. The following authors have furnished very important documents in support of that theory: Dr. Gairdner, of Glasgow (*Brit. Med. Journ.*, June 11, 1887), on vaccinal leprosy. Dr. F. C. Castor, of British Guiana, in his report for 1887, says that under certain conditions leprosy may be contagious, and that it is undoubtedly transmitted by heredity. Dr. John D. Hillis, in charge of the Leper Asylum of Mahaica, British Guiana, in 1889 wrote several pages to show how leprosy is being spread by inoculation (*Journ. Royal Agricultural and Commercial Society*, Demerara). Dr. Boon, of St. Kitts (*Quart. Reports* for 1889), and Governor Robinson, of Trinidad, point out the same fact. Dr. Edw. Arning, of Honolulu, in a letter to Mr. Tebb, is yet more outspoken, and says that there is no mistake about the actual synchronism of the spread of vaccine and of leprosy on the Hawaiian Islands. In another article he writes that, unquestionably, new centers of leprosy developed after vaccination was practised—leprosy, like syphilis, depending for its propagation upon the direct introduction of the virus into the blood. In 1880, Dr. Livening, of Sandwich Islands, pointing to the fact that for thirty years the disease had spread among natives of certain islands where it was previously unknown, says: "It is probable that in a certain stage of the disease it is inoculable." In a letter dated Bergen, Norway, April 9, 1889, Dr. W. G. Armour Hansen, Inspector of Leper Hospitals in Norway, says: "I moreover think that leprosy in most cases is transferred by inoculation. Whether there be any danger of transferring the disease by vaccination I cannot say, as in my country one never is vaccinated from a leprous child, at least so far as we know." Father Damien (*The Lancet*, 1889) attributed his infection with leprosy to inoculation. Dr. Robert Pringle, of the Bengal Army, speaking of the way in which vaccination is practised in the East Indies, says that leprous inoculation will become far more possible, and hence probable, than it may appear at present, unless prompt and stringent measures are taken in Bombay (Letter to *The Times*, June 12, 1889). Sir William Moore, surgeon-general of the Bombay staff (Lecture delivered at King's College, November 20, 1889); Dr. Herdemstam, chief medical officer for Cyprus (Letter to Parliament, March, 1890); Mr. Racker, of Barbadoes (*Agricultural Reporter*, January, 1889); Dr. J. Bechtinger, of Rio de Janeiro (book on the subject published in Vienna); Dr. Robert Francis Black, M.R.C.S., L.R.C.P., Edinburgh; Mr. Michael MacTurck, British commissioner and resident magistrate, British Guiana; Dr. R. B. Emerson, president of the Board of Health of Honolulu, and many others, express the same opinion and give illustrative instances.

Now, knowing one and very likely the most important of all of the causes to which is attributed the spreading of the disease, why are governments so neglectful? They are well aware of the fact that lymph is never secured in sufficient quantities, and that in remote countries, outside of the physicians, many persons are practising vaccination, making use of any kind of lymph. They may do it *bona fide*, for it sometimes requires a well-educated eye to discover leprosy, above all in a child; but it would be better anyhow, under those circumstances, to prohibit any such practice. That is where the apathy of governments becomes criminal.

Venezuela is the only country where segregation is really and effectively compulsory. The law was passed during the presidency of General Guzman Blanco, and in 1880 the Providence Island Hospital was established. There, no matter who one is or what his wealth, if he be recognized to be a leper he is compelled to go to the asylum. Providence Island, about one mile long and one-third of a mile broad, is situated in the narrow part of the Lake of Maracaibo, some four miles from the town of Maracaibo, in the State of Zulia. One is not admitted to the island without a permit from the State government. Anyone that can afford it is authorized to build a little cottage on a given piece of ground. The hospital is a large rectangular building, with a large yard in the center and an inside veranda between the yard and the rooms. Everything is plain and simple, but exceedingly clean. Each room has two doors, an inside window, and its own supply of water; the walls are whitewashed; a hammock, chairs or stools, and a wooden trunk used as a press for clothes are the only pieces of furniture. About 140 lepers live on the island. The average of expenses per head per year has been brought down from $100 in 1886 to about $85 at present. The State of Zulia contributes 6000 bolivares ($1200) for the maintenance of the institution. Voluntary contributions and gifts help in making improvements now and then. A chapel forms one side of the building, and a library is open to all the patients. The institution is managed in Maracaibo by a committee or junta, consisting of seven members. On the island lepers are taken care of by a physician, a chaplain, a manager, four policemen, two cooks, two boatmen, and four or five assistants.

During a sojourn of two years in Maracaibo I often went to the island, where I always found these unfortunate creatures as happy as they can be.

They are well treated, safe from ill-usage, and admit that life is made as easy for them as it can be, considering their miserable condition.

ORIGINAL LECTURES.

NON-VENEREAL SYPHILIS.

A Clinical Lecture, delivered to the Students of the Georgetown Medical College, at the Central Dispensary and Emergency Hospital, of Washington, D. C., on November 14, 1891.

BY HENRY A. ROBBINS, M.D.

LAST week we had the difficulties in the diagnosis of syphilis under consideration. The more you see of syphilis the more you will agree with that Scotch divine who, commenting on the text "David said in his haste, all men are liars," said: "Ah, David! if you had lived at the present time, you would have said that at your leisure."

Years ago it was supposed that syphilis was exclusively a venereal disease, and that the poison was always transmitted by carnal contact. It is well known at the present time, however, that syphilis occurs very frequently from inoculation during operations, from innocent exposure of the lips to the poison by kissing, and other methods equally consistent with the good character of the person affected.

Some years ago, Dr. Bulkley, of New York, read a paper before the New York Academy of Medicine, in which he drew the following conclusions:

"Syphilis is not necessarily a venereal disease, but in a considerable proportion of cases is acquired quite unconsciously, and in an entirely unexpected manner. Failure to obtain a venereal history should not lead to the conclusion that certain lesions are not those of syphilis. The syphilitic virus can be carried a long distance, and after some time cause syphilis in the inoculated. Non-venereal chancres have been mistaken for epitheliomata, and operations for their removal have even been performed. Non-venereal syphilis often shows great malignancy."

A week ago I gave at length a report of the case of a little girl, seven years old, who acquired syphilis in a singular way. After accidentally injuring her hand, suffering an incised wound, her uncle put his mouth to the part, thinking that suction would more rapidly induce healing. A chancre, followed by enlarged glands of the axilla and roseola, ensued. Examination of the uncle revealed mucous patches in his mouth.

I alluded to another case occurring in a Jewish family in which, after the rabbi had performed the religious rite of circumcision on a child, a chancre developed, and subsequently mucous patches were discovered in the mouth of the rabbi.

Dr. M. Rollet, in a chapter of his excellent work on syphilis, mentions the frequent transmission of this disease among workers in glass, who, in blowing bottles, make use of an iron tube, called a *canné*, which passes from mouth to mouth; in consequence of this practice, infections take place, commencing in the mouth.

Dr. M. Hillariet mentions the case of a patient, a lady whose morality was above suspicion, who acquired a chancre of the lower lip, followed by terrible constitutional syphilis. She had drunk from a glass that had been previously used by a woman who was affected by a chancre of the lip. Dr. Hillariet also mentions the case of a favorite medical student who acquired a labial chancre by placing between his lips a pen that had been soiled by his own fingers, previously in contact with ulcerations.

It is a well-known fact that in Cuba the most expensive cigars carry chancre-poison, having been licked with the lips by the roller to make the ends secure. Perhaps this fact may solve the question of the origin of *epithelioma* when the diagnosis and prognosis of certain cases have been so vague and unsatisfactory. I quote the following taken from the *Times:* "A prominent physician told me lately, that from the practice of cigar-makers wetting the wrapper with saliva and biting the end of the cigar into shape, a spread of syphilitic disease was taking place; that he knew of several cases. Somewhat alarmed, I managed to visit a number of factories. Two-thirds of the cigarmakers, I found, daub the whole end of the cigar with their saliva. Thinking that Cuban workmen might not do it, I visited places where they were employed, finding that not only did they use their saliva to make the wrappers stick, but that most of them, before wrapping, bit the end of the cigar into shape with their teeth."

At a clinic held in Paris, at the Hospital St. Louis, Dr. Fournier presented a man who had an indurated chancre of the tonsil, followed by engorgement of the cervical glands and secondary eruptions on the skin. The primary chancre was evidently induced by a simple cauterization with a stick of nitrate of silver which had previously been used on a chancre. In a similar manner Dr. M. Blauchet, who had a large practice in Paris, communicated syphilis to twenty-seven persons in passing a catheter into the Eustachian tube; among others, a young girl of high connections, a pupil of Sacre-Cœur, was infected, and, together with other symptoms, suffered from necrosis of bones of the nose, but recovered good health subsequently. Blauchet had the habit of simply placing the catheter in a tumbler of water after each catheterization, without otherwise cleansing it.

The *University Medical Gazette* says that "the initial lesion of syphilis has been reported a number of times in the literature of medicine as occurring on the eyelids, most frequently upon the free border of the under lid, and at both commissures. The source of infection has usually been due to kissing, a mucous patch in the mouth being the source of the contagion. Chancres have not alone been found in the eyes of adults, but are occasionally found in children. Thus, in an analysis of twenty-one cases of syphilitic lesions of the eyelids made by Griffith (*Medical Chronicle*, 1886), five children of thirteen months or under were affected: in four of them the manifestation was primary, and in one the appearance exactly simulated that of a Hunterian chancre, although the reporter was not able to definitely prove this point. A number of instances of chancres appearing among children in France some years ago led Baudry to investigate the source of infection. This was found in the not infrequent custom among the attendants of these children of attempting to cure inflamed

eyelids by moistening them with saliva. Mucous patches were present in the mouths of these attendants, and the palpebral borders were thus inoculated with syphilitic poison. It is a fact not generally known, perhaps, that among certain ignorant and filthy classes the habit of endeavoring to remove foreign bodies from the eye by means of the tip of the tongue is not an uncommon practice."

Dr. Motz (*Gazette des Hôpitaux*, 128) reports the case of a soldier having an indurated chancre of the eyelid. Under specific treatment recovery took place in nine weeks. A kiss was supposed to have been the cause.

Dr. Lee (*Liverpool Medical and Surgical Journal*, January, 1886) reports the following: "A man had a chancre on the left upper eyelid, accompanied by considerable swelling and induration of the pre-auricular and submaxillary glands on the same side. The patient was strong and healthy, married, aged about thirty-five, a laborer in the Mersey tunnel, and stated that six weeks previously he had gotten some grit in his left eye, which a fellow-workman undertook to remove by licking with his tongue. About a month after this occurrence the eyelid commenced to swell; there had been no discharge from it, and shortly he noticed that a lump began to form on the side of his cheek; he used only domestic remedies, and the eyelid not improving in about a fortnight, he sought advice at the infirmary. Specific treatment resulted in cure.

I have, in my medical scrap-book, notes of several cases of syphilis communicated through the medium of a razor during the process of shaving. I have also found a case of acquired syphilis from the bite of a man. Dr. MacLaren, in his splendid *Atlas of Venereal Diseases*, has a beautiful representation of a digital chancre caused by striking in the mouth a man who was a victim of syphilis, and had buccal mucous patches.

Before bovine virus came into general use, syphilitic virus was undoubtedly communicated through the agency of humanized virus. The literature on this subject is voluminous. Chancres probably resulting from the lascivious kisses of an infected prostitute can be found almost anywhere on the integumentary surface.

The following case is unique: Dr. Leloir (*Annales de Dermatologie et Syphilis*, 1882, Nos. 9 and 10) relates the case of a medical student in whom the initial manifestation of syphilis was situated between the second and third toes of the right foot. The patient was suffering from eczematous fissures between the toes, and acknowledged contact of the affected part with the lips of a woman who was afterward found to be suffering from mucous patches of the mouth.

The following I quote from the *Gazette des Hôpitaux*, December, 1859: Dr. Guényot and M. Gailleton were prosecuted at Lyons for inoculating a child, not affected with syphilis, with secondary syphilitic pus. The inoculation was successful; secondary syphilitic symptoms appeared within two months. They were fined for the experiment, one in the sum of 100 francs, the other in the sum of 50 francs.

Otis says that mediate contagion of syphilis is common. "It may be through the medium of a spoon, a pencil, a cane, a cigar, a kiss, or dental instruments. The accoucheur may acquire it through his finger. Nine cases of syphilis of the finger I published several years since as occurring under my own observation, and I have seen other cases since that time. Besides this, I have seen at least double that number of cases of syphilis where no possible trace of source of contagion could be ascertained. A tumbler, or any article in common use, defiled with the secretions of a mouth harboring a mucous patch, coming in contact with a crack or abrasion of the lips of a healthy person, may communicate syphilis through a resulting lesion, which may pass away unnoticed. Any similar contact with the blood of a person in the active stage of syphilis will communicate it."

Years ago, there was a question whether the blood of syphilitics was contagious or not. To solve this question, Dr. Bargioni, an Italian physician, voluntarily submitted to the experiment. The patient who afforded the material for experiment was a woman, aged twenty-five years, the subject of well-marked constitutional syphilis. Her arm was washed clean, and no eruption existed on that part. The cephalic vein was opened, and some blood was drawn; lint was dipped in it, and applied to the arm of Dr. Bargioni, in which three incisions had been made, just below the insertion of the deltoid. In twenty-four hours the lint was removed. In four days all trace of the inoculation was gone. After a few days he noticed itching, and on looking at the arm there was observed a round papule, of a red color, but no induration around it. The papule gradually increased, and in eight days was of some size, and covered with a slimy scale. Eleven days after its first appearance the glands in the axilla became enlarged. On the sixteenth day these glands were larger; and on removing the scab from the papule a small quantity of serum was found beneath, but no induration around it. On the eighteenth day, there was an ulcerated surface with a crust on it, and a certain degree of hardness at its borders. On the twenty-third day it was larger and harder, as were also the glands. A month after the first appearance of the papule he had nocturnal pains in the head, and observed some enlargement of the cervical glands. A week after this a roseolous rash appeared on the body, and spread all over him, leaving no doubt as to its nature. In another week the sore was not yet disposed to heal, and the glands were larger. The rash then became copper-colored. Mercury was given, and the sore began to heal.

I will now proceed to report some cases in which, as physicians and surgeons, we are more especially interested.

Dr. Wilks, of Guy's Hospital, reports the case of a surgeon who accidentally cut his finger while operating on a man suffering from secondary symptoms, and who himself in consequence took the disease. This surgeon gave it as his opinion that women continue to infect men long after the primary sore has healed.

Diday speaks of the frightful ravages of syphilis in a country village, introduced by a syphilitic infant and propagated by the nurse.

Chancre of the breast is one of the most important of extra-genital chancres. Although it may be contracted by contact with the mouth, or even the genitals of another adult, it is by far the most frequently met with as the result of contagion from mucous patches on the lips of nursing infants.

When attending the clinics at the Allgemeine Krank-

enhaus in Vienna during the years 1877, 1878, and 1879, I attended several "semesters" of Professor Zeissel, one of the greatest syphilographers of the age. This pre-eminent man, we all know, had acquired syphilis while opening a bubo. During the year 1884 he died of cerebral syphilis.

It would be impossible for pen to portray the dangers and horrors of syphilitic infection more graphically than Professor Wm. Goodell has done in a clinical lecture to his students at the University of Pennsylvania. Dr. Goodell says:

"When I was a medical student, one of the members of my class, just before his final examination, broke out, from head to foot, with an unmistakable syphilitic eruption. He was at a loss to account for it, yet his diploma was at first withheld from him, on the ground of immoral conduct. Fortunately he remembered having had a sluggish ulcer on his finger, which, very luckily, he had shown to a member of the faculty, who, however, made light of it. This fact, together with the fact that he had worked during the summer vacation in the venereal wards of a hospital, exonerated him. His diploma was given to him, but he was too much disfigured to go on the stage to receive it. Now mark the history of this man! After taking much medicine, and supposing himself cured, he settled in a Western city, and married. To his great dismay, the first pregnancies successively ended in early miscarriages. Then he put himself and his wife upon a long course of specific treatment. The pregnancy that followed this went nearly to term, and husband and wife were very happy. But the curse was yet upon him. She was prematurely delivered of a syphilitic and dead child. Terribly disappointed and disheartened, the doctor fled from his wife's bedside to an upper room of the house, and shot himself dead.

"I often met in consultation a physician of fine physique, and in splendid health. Unfortunately he delivered a woman whose husband had infected her. That physician is now a wreck, dragging one foot behind him as he hobbles on crutches. It was the old story: first a sluggish and unsuspected sore upon the hand, and next the characteristic eruption, which, like a thunderbolt, revealed the nature of the disease to the unfortunate victim. Then a gummy tumor formed in the brain, followed by aphasia and paresis. Potassium iodide in heroic doses saved his life, but that was about all it did.

"I know two other physicians who caught this horrible disease while in the discharge of their professional duties. One of them lost every hair on his body, from the crown of his head to the sole of his foot. For years he struggled and strove with the poison. But he finally conquered it, and lived to marry, and to have a family of healthy children around him. The other physician had the usual innocent-looking sore on his finger. It hung on obstinately, and for weeks he had his finger in a stall, yet I could not get him to believe that it was specific. Before long he was confined to his house with some obscure chest-trouble, which greatly perplexed his physicians. I could not stand it any longer, and going uninvited to his bedroom I made a strong 'deliverance' of my opinion of his disease. But he laughed me to scorn. A few days later, a magnificent crop of rupia appeared upon his forehead. Then all was clear; and under appropriate treatment he recovered his health and has continued well ever since, but he was ill for a long time.

"The knowledge of these facts has made me keenly alive to the dangers which physicians in general, gynecologists especially, incur in the examination and in the delivery of women. It has also made me very careful to see that all my everyday instruments are kept scrupulously clean, for there is no doubt that careless physicians have unwittingly inoculated their patients by their instruments, and especially by the speculum. Why physicians who contract this disease in the legitimate exercise of their duties should, as a rule, suffer more than those who pay penalty for their immorality, I can explain only in one way. In the former the sore is ectopic, and not being in the usual site, is not recognized early enough to be controlled by local and constitutional treatment. In the immoral, the chancre usually appears on the genital organs, where it is anxiously looked for, and where its identity is unmistakable."

PSORIASIS—ACNE ROSACEA—EPITHELIOMA—TINEA FAVOSA—SYCOSIS—HYPERIDROSIS.

A Clinical Lecture.

By LOUIS A. DUHRING, M.D.,
PROFESSOR OF SKIN DISEASES AT THE UNIVERSITY HOSPITAL.

Case I. *Psoriasis.*—This man, thirty-five years of age, has been affected twenty years, but never seriously, until after an attack of influenza one year ago. His body and scalp show numerous disseminated, scaly, slightly inflamed, erythematous, ill-defined patches, with considerable thickened skin. There are several patches, about the size of a dollar, on the back, and two or three palm-sized patches on his chest, tending to run together. The latter are yellowish, and more inflamed than the others, as a result of the application of chrysarobin ointment. The discoloration and inflammation caused by chrysarobin constitute the great objection to its use, since both skin and clothing are stained, besides setting up an artificial inflammation, unless cautiously and skilfully used. It is a most valuable remedy in this and other skin diseases, and these disadvantages may, in part, be overcome by care; use it sparingly, and not too strong at first, from 5 to 15 grains to the ounce, cautioning the patient as to its properties and dangers. With these precautions, it forms the best local treatment at our command. In this patient, on whom it was used in the proportion of 20 grains to the ounce, the scales have disappeared, and he is already much improved, though the skin is slightly discolored. Small blackish points are observed on his body, due to the staining effect upon the contents of the sebaceous glands. To allay the inflammation the following formula will be ordered:

℞.—Acid. boric. . . . . ℈ij.
Zinci sulph. . . . . gr. ij.
Alcoholis . . . . . f℥j.
Aquæ . . . . q. s. ad f℥iv.—M.
S.—Apply three or four times daily.

After subsidence of the inflammation, we will return to the use of chrysarobin. When psoriasis is localized, external treatment alone should, in most cases, be used;

though, in some cases, constitutional treatment will prove advantageous. Relapses are the rule, but patients sometimes escape. Seborrhea of the scalp differs from this disease, in that it is generally more diffused, and does not present the infiltration of the skin that occurs in psoriasis.

CASE II. *Psoriasis.*—This woman is also suffering from psoriasis. On one leg we notice small, red, circumscribed, and slightly scaly spots, while on the other leg there is a large, indurated, fissured, and inflamed lesion, showing no signs of the characteristic scales, and which, but for the existence of the lesions on the other leg, might be diagnosticated eczema. The disease has existed for two months, and has had no treatment. Remedies of different strengths are required for the two legs. For the small lesion an ointment of chrysarobin, 15 grains to the ounce, will be ordered; while for the larger, as it is fissured and inflamed, the following ointment will, for the present, be ordered:

℞.—Acid. salicylici . . . gr. xij.
Zinci oxidi . . . . ℥jss.
Petrolati . . . . . ℥j.—M.

CASE III. *Acne rosacea.*—This woman, aged thirty-five years, who is large and stout, has been under treatment for several months, and is much improved. Some cases of this kind are easily relieved, while others are extremely obstinate. It is a compound disease made up of acne plus dilatation of the capillaries, or rosacea.

There exists a disturbance not only of the secretion of the glands, but also of the circulation around the glands.

Treatment, in ordinary cases, is much the same as in acne. The following has been used:

℞.—Ung. sulphur. . . . . ℥j.
Resorcin. . . . . ℥ss.
Acid. salicylici . . . gr. xx.—M.

It does not irritate, but improvement is now not so marked as formerly, hence we will continue the foregoing at night, and order the following lotion to be used in the morning:

℞.—Sulphur. precip. . . . ℥j.
Etheris . . . . . f℥vj.
Aq. Cologn. . . . . f℥iv.
Alcoholis . . . q. s. ad f℥iv.—M.

S.—To be shaken and applied for fifteen minutes each morning.

This treatment will be continued for several days. The lotion is a valuable formula, in some cases proving of more benefit than any other remedy. The method of combining remedies, by using dissimilar ones night and morning, is frequently found to be of distinct advantage. Then, too, much may be accomplished by properly directing a patient, and particularly in acne is this true. Patients should be made familiar with the method of using a remedy, whether to be applied with or without friction, the length of time to rub in an application, etc. Frequently, when this is neglected, we find patients not carrying out the treatment properly, thus at times explaining the failure of good remedies. If the case be a marked one, the patient should be seen often, and the progress of the disease watched under treatment.

CASE IV. *Disseminated glandular epitheliomatous degeneration on the neck.*—The patient, an elderly man, states that these lesions have been forming for fifteen or twenty years. The disease is a superficial, epithelial degeneration, disseminated, breaking down in places, forming small ulcers. It is the mildest manifestation of epithelioma, and may continue in this way for years, or it may break down into larger and more active lesions, if allowed to pursue its natural course. Much may be done for this mild expression of the disease. An ointment of sulphur, at first 30 grains to the ounce, and later stronger, will be ordered, to be rubbed in twice daily. Sulphur soap may be used in place of ordinary soap. Resorcin is also useful in these cases. This tre atment tends to arrest the abnormal epithelial proliferation.

CASE V. *Epithelioma of the nose.*—This woman, sixty-five years of age, had a dime-sized ulcer on the side of her nose, which was curetted four weeks ago. The wound has since been healing. She has been using a dressing of resorcin cerate, 30 grains to the ounce, which was found to be too stimulating and was discontinued. Resin cerate was then ordered, and has proved beneficial. Granulation should not be allowed to cease too soon, or the resulting scar will not be full and shapely. The wound is now discharging freely, and we will endeavor to keep up granulation by using a wash of resorcin, 20 grains to the ounce.

CASE VI. *Tinea favosa of the scalp.*—This boy, an Italian, ten years of age, has a contagious, parasitic disease of the scalp, characterized by small, cup-shaped, pale-yellowish crusts, each perforated by a hair. The crusts in crease in size, forming irregular-shaped masses, which have a peculiar, characteristic, mouse-like odor. The hairs become much diseased, dry, and brittle, or the follicles suppurate, and the hairs fall out, leaving scars. The disease is only occasionally met with in this country. It usually occurs among the poorest class, and chiefly in foreigners.

Treatment is difficult when the disease is extensive. It pursues a decidedly chronic course, lasting for years or for a life-time. This boy has been using the following as a soap:

℞.—Sulphur. . . . . ℥ij.
Acid. salicylici . . . gr. xxv.
Soft-soap . . . . ℥j.—M.

Besides this, he is applying a wash of sulphurous acid, and the officinal sulphur ointment, under which treatment he is somewhat improved. The disadvantage of treating this disease lies in the fact that it is found in this class of people; it is extremely difficult to have a line of treatment thoroughly carried out. An ointment of betanaphthol, 3j to the ounce, is useful, and in this case will be prescribed at an early day.

CASE VII. *Sycosis.*—The lesion, on this man, has existed for four months, and consists of papules and papulopustules, each perforated by a hair, together with marked thickening and inflammation, involving the bearded region of the face. This disease is met with in all grades of society. The lesions appear close together, and tend to set up an area of follicular inflammation, accompanied usually with burning. In tinea sycosis the hairs are soon involved, becoming dry, brittle, and loose,

falling out spontaneously, or they may be readily extracted. Tinea sycosis, moreover, usually pursues a more rapid course. Sometimes it is difficult to distinguish between the affections without the aid of the microscope. The disease is obstinate, and must be properly treated. This man has a subacute type, which calls for stimulating remedies, such as the following:

℞.—Zinci sulphatis } āā . . grs. x.
Potass. sulphidi }
Aquæ . . . . . f℥iv.—M.

S.—Apply to face three or four times a day, for a few days.

After which use sulphur ointment (℥ij to the ounce), rubbed in with friction. The face should be shaved every other day. Ichthyol and resorcin, in form of lotion or ointment, may be used locally with advantage. Constitutional treatment, as a rule, is of little value. Some cases require stronger and more penetrating remedies, as salicylic acid with sulphur ointment. Never aggravate the disease by remedies, and as soon as increased inflammation sets in, stop the remedy. If the treatment being used does not show improvement in three or four days, it is advisable to make a change.

Case VIII. *Hyperidrosis of the soles.*—The plantar surfaces of this young man's foot have been affected for six or eight years. It is a functional disease of the sweat glands, and is usually chronic. Bromidrosis, or stinking sweat, is at times present, and may be so marked that the patient cannot occupy the same room with other persons. Astringent lotions and dusting powders are indicated. The patient has, for the past week, been dusting with boric acid, after washing the feet several times each day and thoroughly drying, and returns to-day greatly improved.

CLINICAL MEMORANDA.

A CASE OF IMPERFORATE ANUS; SUCCESSFUL OPERATION THROUGH PERINEUM.

By ALFRED E. BRADLEY,
FIRST LIEUTENANT AND ASSISTANT SURGEON, U. S. A.

Baby F., a female, was born July 22, 1891, at midnight. On the following day it was noticed that the infant had no anus. The child was sent to the writer through the kindness of Dr. F. A. Halliday, Acting Assistant Surgeon U. S. A., whose case it was. No tumor or fluctuation could be found; abdominal pressure caused no bulging, and in no way could the presence of the bowel be determined. The perineum was smooth, the raphe extended from the vulva to the coccyx; not even a dimple marked the anal site. The genital organs were apparently perfectly developed; urination was normal; the infant was fairly well developed, but was irritable, and evidently in distress; the abdomen was distended, and the superficial veins passing to the anterior thorax were prominent and tortuous. The child had taken the breast, but was loth to do so for some twenty-four hours prior to the operation; vomiting had taken place several times, but consisted only of the milk taken. Its weight was not more than six pounds, and it was not particularly well nourished.

An operation through the perineum was decided upon, and was agreed to by the parents. If the perineal route had failed, preparations had been made to do an inguinal colotomy.

The child was placed in the lithotomy position, and, with the assistance of Dr. Halliday, the operation was performed on the morning of July 25th, the child being then fifty-eight hours old. No anesthetic was given; the only pain the infant seemed to experience was while the incision was being carried through the skin. This incision was about seven-eighths of an inch in length, and made antero-posteriorly. Dissection in the line of the coccygeal and sacral curve was carefully and cautiously made with scalpel, grooved director, and probe-pointed scissors, the little finger being employed as a probe. After going in to the depth of about an inch, an exploring-needle was carefully used; after its introduction about an inch further the escape of gas showed that the bowel had been punctured, and that the operation could be carried on with probable success. Further dissection to a total depth of about two inches disclosed the rectal pouch distended at the bottom of the incision. It was grasped by forceps, a tenaculum introduced, and the bowel then opened by an incision about half an inch long. This was followed by a gush of meconium and some gas. The quantity voided seemed enormous, and the relief given the infant was immediately evidenced by a quiet sleep.

The incision and lower bowel having been cleansed by injecting warm water, the rectum was carefully drawn down by the tenaculum and sutures introduced. The first was passed through the margin of the perineal incision, through both lateral walls of the rectal pouch, and out through the margin of the incision on the other side. When the loop in the lumen of the rectum was drawn down and divided, the bowel could be easily manipulated by the two lateral sutures thus formed. As nearly as possible the edges of the incision into the rectum were brought into apposition with the incision through the skin, and the sutures tied. In, all seven sutures were thus introduced, and the rectum was then continuous with the perineal opening. This opening was much diminished in size by the slight upward traction of the bowel, but mostly by the action of the external sphincter, which threw the tissues about the incision into distinct corrugations. Throughout the operation the writer was impressed with the tremendous size of his hands and instruments as compared with the extremely small field of operation. The child stood the operation well; there was no evidence of shock or collapse; it went quietly to sleep, and after awakening it took the breast eagerly.

On July 30th, though there had been previously a slight diarrhea, there were but two passages, beginning to be normal in appearance. The stitches all pulled out from the bowel; there were no adhesions of the bowel to the skin. The wound looked healthy, and granulations were springing up. The bowel was adherent at a point about three-fourths of an inch above the perineal incision. The child suckled heartily, slept well, and its condition was in every way favorable. The wound was dusted with equal parts of iodoform and boric acid.

On August 2d the child was still doing well, suckling, sleeping, and thriving. There appeared to be some in-

continence, but there was still certain control over the sphincter. The parts were healthy. A rectal bougie of tallow, about two inches long, was introduced twice daily to overcome the tendency to cicatricial narrowing.

On September 20th the child was growing and thriving, with two or more healthy passages each day. Cicatricial hardening and contraction had taken place, so that it was difficult to introduce even the tip of the little finger. The resisting ring seemed firm and fibrous. Tallow bougies were used, but of too small diameter. A tight-fitting bougie caused considerable pain. Bougies five-eighths of an inch in diameter at the base were slowly introduced and allowed to remain about five minutes. These were to be gradually increased in diameter until the desired result was obtained. If these should prove ineffectual, the ring of narrowing should be nicked by a scalpel, and gradual dilatation be maintained during and after the healing.

On December 18, 1891, when last seen, the child was doing remarkably well. It had been necessary to dilate the cicatrix on account of the extreme contraction; this was done under chloroform, the narrowed ring being nicked by a scalpel in several places, and this followed by forcible dilatation with the little finger. There had been considerable reaction, and for a few days it seemed that recovery would be impossible. Healing took place, however, and the perineal opening became much more patulous, and, though narrow, it seemed to be sufficient. The bougies were still employed, for the tendency to narrowing still existed. The child was large and healthy, but it was with difficulty kept free from constipation, and required constant watching. There seemed to be little or no incontinence.

FIBROID TUMOR OF THE UTERUS.

BY W. H. MILLER, M.D.,
OF LITTLE ROCK, ARK.

CALLED to see Mary M., a colored woman, forty-three years old, married and the mother of three children, I learned that she had not menstruated for ten months or a year, and that she was having excessive hemorrhage from the vagina. Upon examination, I found a tumor in the vagina, about the size of the normal uterus, tightly grasped between the lips of the cervix.

I introduced a speculum, and ascertained that the hemorrhage came from the tumor, which had all the appearances of a fibroid of the uterus. I succeeded in checking the hemorrhage with tampons moistened with hydrastis; these I allowed to remain in the vagina for twenty-four hours, when I removed them and found the hemorrhage but slight. Inversion of the uterus had been diagnosticated; repeated attempts had been made to replace the mass, but had proved unsuccessful. For purposes of confirmation or correction, I attempted to pass a sound into the uterus. The procedure was attended with difficulty, on account of the extensive base of the tumor; but, once finding an opening into the uterus, the sound was readily passed for nearly three inches. I was thus fully satisfied that the condition was not one of inversion of the uterus. The tumor was hard and non-painful, bleeding freely when punctured. The patient's family history was good; she said that about eight years previously she had been operated upon for a tumor in the same situation, and that the growth was not entirely removed. I, therefore, concluded that the mass must be a fibroid tumor of the uterus.

The tumor could not be moved from side to side, as is the case with pedunculated fibroids; hence I concluded that it must have a broad base; this opinion I afterward found to be correct, as the attachment of the tumor extended from just within the external os to the fundus of the uterus, and laterally about two fingers' breadth.

I prescribed fluid extract of ergot, f℥ij, *per rectum*, three times a day, to prevent a recurrence of the hemorrhage, and to facilitate expulsion of the tumor, which I determined to remove as soon as possible. I was compelled to delay operation for some time on account of the development of an acute phlebitis in the left lower extremity. The tumor seemed to diminish in size and become softer, and there was a slight discharge from the uterus. The patient had some fever, which was controlled by irrigation of the uterus with hot water and bichloride of mercury.

On June 13th, with the assistance of Drs. Lindsay and Dickinson, I operated on the patient in the Sims position; and with the Sims speculum in the vagina I attempted to pull the tumor down, but failed on account of extensive adhesions of the uterus. I then passed a shawl-pin through the tumor to prevent the wire of the écraseur from slipping. I attempted to pass the écraseur around the tumor, but failed on account of the large extent of attachment. Using the fingers of the left hand in the vagina as a guide and to prevent injury to the uterus, with a pair of curved scissors I cut into the capsule of the tumor at its attachment to the wall of the uterus and enucleated the growth. The hemorrhage was slight, and after removing, by means of the curette, such particles as remained, I packed the uterus with iodoform cotton, and placed the patient in bed. Recovery was prompt and satisfactory. The woman's general condition improved greatly; her stomach, which previously to the operation had been irritable, gave her no further trouble. Previously to the operation the patient was confined to bed; the repeated hemorrhages had rendered her anemic. She now goes about attending to her household duties, and says that she feels better than she has for years. The cavity of the uterus measures about three inches in length; the os is about normal. The woman menstruates regularly, the period lasting about two days; it is free from pain, and the flow is not excessive.

I am aware that there is nothing new or novel in the case that I have reported. Perhaps the treatment may be criticised by electricians, who may say that I should have tried electricity before resorting to an operation. I think that electricity may be beneficial in cases of intramural fibroids when the growths cannot be removed without at the same time removing more or less of the uterus, or otherwise injuring that organ; but in all cases in which the tumor is accessible I should resort to the more certain procedure of immediate enucleation.

It may be suggested that with a woman forty or forty-five years of age an operation was not indicated, but that the menopause should have been awaited; but the condition of the patient was such that delay would have

been dangerous. In the next place, fibroids tend to defer the menopause.

A large fibroid tumor occupying the vagina may readily be mistaken for an inversion of the uterus. If in a non-corpulent person there should be an inversion of the uterus, we usually find a cup-shaped depression in the space behind the pubes usually occupied by the normal uterus; while in case of fibroid tumor palpation will disclose the presence of a uterus rather larger than normal. By rotating the tumor, if it be pedunculated, we find that the uterus rotates but little or not at all. The diagnostic point is the introduction of the sound. If in a case of long standing we can pass the sound through the cervix and beyond the mass in the vagina for a distance of two or three inches, we can say, without fear of contradiction, that the case is one of fibroid tumor, and not of inverted uterus.

I remember a striking case in which a mulatto woman presented a large tumor completely filling the vagina. Upon being directed to stand up and to bear down, she succeeded in completely expelling the tumor, which was an inverted uterus of long standing, which extended about half-way to the knees.

PAPILLIFEROUS FIBRO-CYSTIC ADENOMA OF ABERRANT BREAST NODULE.

BY W. S. FORBES, M.D.,
PROFESSOR OF ANATOMY IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

THIS comparatively rare form of tumor was taken from a patient brought to me by Dr. Wm. Harris, of Hamburg, Pa.

Mrs. S., forty-eight years old, when married, at the age of twenty-eight years, weighed 128 pounds. She now weighs 385 pounds. She has a younger sister who weighs 300 pounds, and who has borne two children, now young women, of twenty-two and twenty-four years of age. Mrs. S. has never been pregnant; she has always menstruated with regularity, without trouble, and continues to do so.

When examined December 18, 1891, a tumor was found in the left upper quadrant of the left breast. Both breasts were huge and pendulous.

The patient had observed a lump in the left breast for ten years, but only in the last twelve months had it begun to enlarge. The tumor appeared to be a fibroma lodged in a mass of fat, having no bands binding it either to the pectoral wall or to the mammary gland. After extirpation there appeared at least three inches of fat between the tumor and the mammary gland, and about the same thickness of fat between the tumor and the middle of the lower border of the neighboring great pectoral muscle.

There was no difficulty in removing the tumor. The patient returned to her home in ten days perfectly well.

I asked Dr. Coplin, Demonstrator of Pathological Anatomy in the Jefferson Medical College, to examine the specimen. The following is his report:

The tumor is irregular in outline, the sides and borders covered by fat. Its weight is 109 grams (nearly 3¼ ounces), and it measures in its longest axis 8.5 cm. (3 inches), in width 6.5 cm. (2½ inches), in thickness 4.5 cm. (1¾ inches). Upon section it cuts hard and creaks slightly under the knife. The cut surface shows several small cysts, varying in diameter from 0.5 mm. to 2 mm. Their outline is regular; some are round, some ellipsoidal, and a few semilunar, with projecting masses extending into, and entirely filling, the cavity. Where any fluid is present it is clear and viscid, closely resembling egg-albumin. Sections made through different planes show these cysts to be restricted to an area slightly oblong, and about 3 cm. (1⅛ inches) in diameter. This mass constitutes the tumor proper, with outlying bands of fibrous tissue.

Microscopic examination shows these cysts to be lined by cylindrical-celled epithelium, the masses projecting into the cysts being dendritic in character, with, in some, the appearance of branching. The stroma is a hard, dense, fibrous tissue, with here and there well-marked, but poorly developed, acinous-gland nodules, varying from one to three acini, their walls lined by flattened and poorly developed epithelium. The vascular supply to the growth has been abundant, and into some of the cysts hemorrhage has taken place.

The tumor is a papilliferous fibro-cystadenoma, a comparatively infrequent tumor of the breast. Among my sections I have a slide of an identical tumor. The late Prof. S. W. Gross brought the slide from abroad. These are the only specimens of this form of fibro-adenoma that I have seen.

From the position of the tumor and its histology I infer that it is from an aberrant breast nodule. These are not so rare as we are often led to believe, and when present are extremely liable to the development of neoplasms, for the most part malignant in character. I have a photograph of a case of carcinoma of aberrant breast nodule from a case at the clinic of the Jefferson Medical College Hospital several years ago. When the tumor was removed I found that it had no histologic connection with the mammary gland proper, which had been removed as a precautionary measure. The nearest gland lobule to the growth was fully two inches from the neoplasm, sections of which not only demonstrated, as in this case, the presence of gland tissue, but also that the entire aberrant breast had not been invaded by the neoplasm.

I have examined three cases of outlying breast structure, and all, strange to say, on the left side.

CHRONIC OSTITIS AND ABSCESS OF THE TIBIA OF LONG STANDING.

BY G. FRANK LYDSTON, M.D.,
OF CHICAGO, ILL.

THE following case appears to me a most interesting one, as showing the prolonged duration of chronic inflammation of bone, and the liability to the intercurrent formation of abscess.

The patient, a gentleman forty years of age, suffered a fracture of the tibia when seven years of age. Whether the fracture was compound or not he does not know, but I infer from his history that it was. It was followed by severe inflammation and necrosis of a portion of the bone. Ever since this early accident, he from time to time has experienced more or less pain at the site of the fracture, which was near the junction of the lower with the middle third of the tibia, and slight

pressure has always been sufficient to make him wince. He states that ever since the accident the lower portion of the bone has been quite tender, and has troubled him a great deal during change of weather. About six years ago he began to have pain in the upper portion of the tibia, principally marked at the articular extremity; more or less swelling was perceptible, and has continued to the present time. There have been occasional exacerbations, with quite acute pain. There is no history of syphilis, or any infectious disease, save scarlet fever in his youth. During the exacerbations of pain and swelling the patient has been compelled to use crutches. Within the last few weeks the pain has been exceptionally severe, and the difficulty of locomotion more marked than at any previous time.

At present the entire tibia is swollen, its diameter being fully double the normal; the muscles of the limb are atrophied from disuse, and possibly the reflex effect of the osseous inflammation and consequent disturbance of nutrition; there is excessive tenderness over the tibia, particularly marked at its upper and inner aspect. In this situation a marked nodular swelling exists, indicating a subperiosteal bony deposit. Another spot of a similar character is discoverable near the site of the old fracture. Numerous cicatrices adherent to the bone are present over the anterior surface of the tibia at points from which the patient says dead bone has been removed, or has escaped spontaneously from time to time.

The diagnosis is chronic ostitis, with osteo-sclerosis of considerable extent, and a probable abscess (possibly a sequestrum) in the upper cancellous extremity of the bone.

A free incision was made in the entire length of the tibia. The periosteum was found greatly thickened throughout. Subperiosteal nodes were discovered at the site of the thickening described; these were perceptible before the operation. The periosteum was peeled back and the bone exposed, and found to be of the peculiar ivory-like consistency and appearance characteristic of osteo-sclerosis. After considerable gouging and chiselling through the hard, ivory-like structure, an abscess was exposed in the upper extremity of the bone, which contained about a tablespoonful of moderately thick pus and was lined with a thin layer of granulations, and was evidently of quite recent formation. This abscess was probably tuberculous. No examination for bacilli was made, however. It was probably the result of a secondary tuberculous infection. The cavity was thoroughly cleaned out, and the bone drilled with a small drill in various directions surrounding the cavity. A linear osteotomy was performed through the lower portion of the bone, and the subperiosteal nodes thoroughly chiselled away, with removal of enough of the ivory-like bone beneath them to insure repair. The cavity is filling up nicely, and the pain is completely relieved. The result, undoubtedly, will be restoration of the limb to its normal degree of usefulness.

DIAGNOSIS OF FRACTURE OF THE FEMUR.

By W. M. L. COPLIN, M.D.,
DEMONSTRATOR OF PATHOLOGY IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

IN injury of the femur I wish to propose a method for determining the presence of fracture, more particularly intra-capsular or extra-capsular, with suggestions for its use elsewhere.

This method presents the advantage of determining the preternatural mobility in the direction of the axis of the bone. Allis's method, or rather the relaxation of the femoral fascia to which he has called attention, is suggestive of mobility upward of the trochanter, but does not in the least measure the degree of displacement, and may indicate only the fracture of the trochanter. In the method of measurement that I propose, the anterior superior spine of the ilium is taken as the fixed point on the pelvis and the inner condyle of the femur as the most suitable point on the extremity. Three measurements are made, which may be designated as: 1. Measurement of repose; 2. Measurement of tension; 3. Measurement of compression. The measurement of repose is made by taking the distance between the two points already given while the limb is lying quiet and in its characteristic position. The measurement of tension is then taken by making firm and somewhat prolonged extension in the axis of the limb; after which the measurement of compression or counter-extension is made, in which any shortening may be encouraged by slightly favoring the upward displacement of the lower fragment. This method of measuring is applicable to any and all fractures of the femur, and will afford corroborative evidence of fracture, except in the following cases: 1. Impacted fractures of either end of the femur. No information could be obtained by measurement in impacted fractures, at least by different measurements, and the objection advanced, that attempts at this form of measurement must break up impactions, cannot be considered as of more bearing than any other effort to diagnosticate a fracture of the femur; for example, attempts to obtain crepitus must be equally dangerous, as would also any attempt to ascertain the presence or absence of rotation of the fragment. 2. Fracture of the greater trochanter. Measurement, as suggested, would be quite useless, but if the measurement be made from the crest of the ilium to the trochanteric fragment there will be no alteration in the measurement, no matter how violent the attempt at extension or compression, provided the fracture is complete and the periosteum not retaining the two fragments in apposition.

I can but briefly outline this method of determining longitudinal mobility, and in the femur the lessened arc of rotation could be measured by taking a point on the pubic bone and measuring from that to the trochanter in complete eversion, followed by measuring in complete inversion, the difference marking the two arcs of rotation on the respective bones. If material difference between the two bones is discernible, there would be reason to infer that the two radii must be different. A similar measurement could be made from behind, taking a suitable point on the sacrum and measuring posteriorly to the right and left. This method may be found extremely useful in many forms of fractures elsewhere than in the femur, and will suggest itself whenever it can be used.

Quatrefages, a distinguished French physician and naturalist, died recently, in the eighty-second year of his age.

MEDICAL PROGRESS.

Aneurism of the Heart, with Symptoms of Angina Pectoris.—Mackenzie and Williamson (*Medical Chronicle*, xv, 5, p. 302) report the case of a man aged fifty-eight, who, without the history of a frank attack of rheumatism, for three months presented symptoms of angina pectoris. On walking fast and during the paroxysms of pain there was increased secretion of saliva referred to the left side of the mouth. There was tenderness in the precordia and over the second dorsal vertebra. The sounds of the heart were faint, the first soft; but no murmur or other abnormality was detected. The patient suddenly expired while engaged in his ordinary pursuits. When the chest was opened, the pericardial sac was seen to be greatly distended. Incision disclosed the presence of a large quantity of clotted blood. On the posterior aspect of the left ventricle, about midway between the apex and the auriculo-ventricular groove, and about a quarter of an inch from the inter-ventricular groove, the wall of the heart was thinned in an oval area, at the lower part of which was a minute linear rupture. On the inner aspect of the ventricle, at a corresponding situation, was a pouch-like depression containing small, recent blood-clots. The floor of the aneurism was apparently constituted only of the endocardium and the visceral pericardium. The edges of the mitral leaflets were slightly thickened; the attached margins of the aortic valves were atheromatous. The sinuses of Valsalva, the coronary arteries, and the ascending aorta were also atheromatous. On microscopic examination the cardiac muscle appeared normal. It is believed that softening of a circumscribed area of the muscular structure of the heart resulted in consequence of the thrombotic obstruction of a branch of the coronary artery, with secondary aneurismal dilatation.

Pneumonotomy and Pneumonectomy.—In a paper read before the College of Physicians of Philadelphia, Willard (*University Medical Magazine*, iv, 5, 1892, p. 334) expressed the view that the entrance of air into the pleural cavity is a far more serious matter, as regards collapse of the lung and of the patient, when the pulmonary tissues are normal than when they are diseased. In dogs, incision and removal of portions of the lung were well borne; hemorrhage was free, but was arrested by packing. Adhesion of the parietal and visceral layers of the pleura was readily secured by means of sutures; the resulting pleurisy was slight. The practical conclusions to be drawn are that incision into tuberculous or gangrenous or suppurating pulmonary tissue can be safely undertaken. In case of gangrene and of abscess better results are to be expected than from other methods of treatment.

Tuberculosis of the Pericardium.—At a recent meeting of the Pathological Society of London, Rolleston (*Lancet*, No. 3558, p. 1042) presented the heart and pericardium of a child, nine months old, that had died with tuberculous meningitis. Lungs, spleen, mesenteric and bronchial glands contained caseous tubercles. The bronchial glands were adherent to the pericardium. The pericardial sac was enormously enlarged. Externally it was red and rough. When opened, about three ounces of clear, yellowish fluid escaped. The parietal layer of the pericardium was everywhere greatly thickened and rigid. There were no adhesions between the visceral and parietal layers. Microscopically, the thickened tissues were found to consist of newly formed fibrous tissue containing bloodvessels, tubercles, giant-cells, and tubercle-bacilli.

Removal of the Uterus in Puerperal Peritonitis.—Smith (*Amer. Journ. of Obstetrics*, 1892, xxv, 169) has recorded the case of a woman, thirty-five years old, delivered by a midwife. The placenta being retained, efforts at manual removal had been made. Symptoms arising that made doubtful a diagnosis between septicemia, appendicitis, and pyosalpingitis, abdominal section was performed, but nothing abnormal was found in connection with the peritoneum, oviducts, or vermiform appendix. It was decided, nevertheless, to remove the uterus. The operation was attended with no special complication, and the subsequent course of the case was uneventful. The removed organ was found to contain remnants of placental tissue in process of decomposition.

The Infectiousness of Carcinoma.—Schopf (*Wiener klin. Wochenschr.*, No. 45, 1891, p. 840) has recorded the case of a woman, fifty-two years old, in which, on account of carcinoma of the body of the uterus, vaginal extirpation was practised. The large size of the uterus necessitated the performance of episiotomy. At either cornu superficial gelatinous infiltration, and at the internal os a soft mass as large as a hazel-nut, were found. Three months after the operation neoplastic nodules were found in the lines of incision that had been made to facilitate the extraction of the uterus. The inference is that local infection took place as a result of contamination by cells or fluid, or both, in the course of the operation. The patient died somewhat later from a metastatic growth in the liver.

Double Optic Neuritis following Influenza.—Lee (*Liverpool Medico-Chirurgical Journal*, No. 22, p. 44) has reported the case of a blacksmith, sixty years old, in which three weeks after an attack of influenza failure of vision appeared, and progressed to blindness. There was nothing abnormal in the urine, and there were no evidences of disease of the nervous system. On ophthalmoscopic examination moderate optic neuritis was found on both sides, disproportionate to the degree of impairment of vision. Under treatment by means of mercuric chloride, potassium iodide, and strychnine, some improvement took place, though secondary atrophy resulted.

Chloroform as an Anesthetic.—As the result of an experience of forty years in the Rotunda Hospital, Dublin, with the anesthetic employment of chloroform, covering many thousands of cases, Atthill (*British Medical Journal*, No. 1620, p. 110) expresses the opinion that, with due care and attention, if the anesthetic be pure, if a proper inhaler be used, if the respiration and pulse be watched, and if a needful degree of anesthesia be steadily maintained, the use of chloroform is safe, certainly quite as safe as the use of ether, while its effects

are infinitely less disagreeable to the patient, both during and subsequently to inhalation.

The Union of Severed Fingers.—At a meeting of the Berlin Medical Society, GLUCK (*Deutsche medicin. Wochenschr.*, No. 46, 1891, p. 1273) presented a butcher who had accidentally severed the terminal phalanges of the ring and middle fingers of the left hand by means of a cleaver. As soon as seen, the resulting wound was disinfected and the parts were carefully sutured. Union took place and was perfect a year and a half later.

THERAPEUTIC NOTES.

Carbolic Acid in Influenza.—SIMSON (*British Medical Journal*, No. 1621, p. 171) reports the successful treatment of many hundreds of cases of influenza by means of carbolic acid. The following is a useful combination:

℞.—Acid. carbolic. pur. liquid. . . ♏ij.
Syrup. simplicis . . . . ♏xl.
Tinct. cardamom. comp. . . . ♏x.
Spts. chloroformi . . . . ♏x.
Aquæ menth. pip. . . . ad f ℥j.—M.

S.—For an adult. To be taken every four or six hours.

The powder of opium and ipecacuanha, in ten-grain doses, was employed to induce sleep and promote perspiration. If cough was troublesome, a mixture containing about gr. $\frac{1}{12}$ of morphine, ♏ v of dilute hydroboric acid, ♏ ¼ of pure chloroform, and sufficient of syrup of lemon and water to make a dram, was employed as required.

Suppositories for Chronic Prostatitis.—For chronic prostatitis, OBERLANDER recommends the employment of a suppository containing—

℞.—Iodoformi . . . . . gr. vij ss–xv.
Solve in
Ol. amygdal. dulcis . . . q. s.
Adde
Ol. theobromæ . . . . q. s.
—ut ft. suppos. no. x.

S.—One to be introduced at night following an intestinal evacuation.

The oil of sweet almonds increases the absorbability of iodoform. The proportion of iodoform in each suppository is slowly increased from three-quarters of a grain to a grain and a half. In susceptible individuals larger quantities may occasion toxic symptoms.—*Deutsche med. Wochenschr.*, No. 53, 1891, p. 1435.

The Cure of Pulmonary Tuberculosis.—In an interesting address before the Medical Society of London, BURNEY YEO (*British Medical Journal*, No. 1620, p. 106), after considering the conditions of cure in pulmonary tuberculosis and referring to the utility of climate, air, food, and exercise in treatment, added that he had observed some excellent results from the employment of rectal injections of sulphuretted hydrogen, as also some good results from the employment of tuberculin. Of the latter he expressed the opinion that it would survive in a modified form. Antiseptic medication, faithfully employed for long periods, exerts a favorable influence upon the course of pulmonary tuberculosis. For internal administration the best agents are creasote and guaiacol.

The Treatment of Influenza.—In a lecture on influenza, BACCELLI stated that in cases marked by bronchial distress, concurrently with a feeble heart, camphor is decidedly useful in the first stage. Four grains of camphor in fifteen minims of olive oil may be injected beneath the skin every three or four hours. If camphor fail, injections of ether often succeed admirably. In other cases injections of strychnine, in doses ascending from a thirtieth of a grain every twelve hours, will often tide over a crisis. To sustain the vital powers hot wine may be given in small quantities at short intervals. In the gastro-enteric variety of influenza in the young and strong, ipecacuanha may be employed to induce emesis. When the respiration is embarrassed striking benefit is often derived from inhalations of oxygen.—*Lancet*, No. 3569, p. 220.

The Treatment of Carcinoma.—At a recent meeting of the Royal Society of Physicians of Vienna, ADAMKIEWICZ (*Wiener klin. Wochenschr.*, No. 47, 1891, p. 888) presented a case of epithelioma of the inner angle of the right eye, in which cicatrization had taken place in the course of treatment by means of subcutaneous injections of a substance called cancroin that, it was claimed, exerted a specific influence upon carcinoma.

BILLROTH, KAPOSI, DITTEL, and others, however, maintained that the progress of the case was not unusual and were unwilling to admit any specific action or curative result not to be obtained by other methods of treatment.

For Baldness.—One of the best combinations in the treatment of baldness consists of:

℞.—Pilocarpinæ hydrochlorat. . gr. v.
Otto de rosæ . . . ♏viij.
Olei rosmarini . . . f ℥iv.
Liniment. cantharid. . . f ℥iv.
Glycerini pur. . . . f ℥j.
Olei amygdal. dulcis . . f ℥ij.
Spts. camphoræ . . . f ℥iij.—M.

S.—To be rubbed well into the scalp, night and morning. WHITLA.

The Relief of Vomiting.—KENNY (*British Medical Journal*, No. 1618, p. 16) has reported the case of a parturient woman, in whom he overcame obstinate vomiting, resistant to other means of treatment, by the application of a cantharidal blister over each pneumogastric nerve at the anterior border of the sterno-mastoid muscle.

Ammonium Bromide and Antipyrin in Epilepsy.—In a second series of cases reported, POTTS (*University Medical Magazine*, iv, 5, 1892, p. 345) confirms the favorable results previously obtained in the treatment of epilepsy by means of a combination of ammonium bromide (twenty grains) and antipyrin (eight grains).

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 5, 1892.

EXPERT TESTIMONY.

DISCUSSION of the much-discussed questions connected with the status in judicial proceedings of the so-called "medical expert," and his testimony, has been reawakened by a recent trial in New York.

We do not wish to comment at this time upon the testimony offered in the Harris trial, for the reason that an official report is not in our possession; while one of the eminent physicians who testified for the defence, PROFESSOR H. C. WOOD, of this city, has publicly stated at a meeting of the College of Physicians, that "the nonsense telegraphed in his name all over the country" was not uttered by him. Nevertheless, the fact remains, that in a case in which the life of the prisoner was at stake, testimony in direct conflict was given for the prosecution on the one hand, and for the defence on the other hand, by medical experts of unblemished reputation and of the highest rank as scientific men and teachers. Under such circumstances, what course is an intelligent juror to pursue? When suspicion of venality attaches to an expert witness, a jury can honestly ignore his testimony; but the most degraded of medical men would hardly sell himself to the prosecution in a criminal case; and it might well be in every instance, as it undoubtedly was in the recent trial at New York, that the personal and scientific character of the expert witnesses for the defence should be beyond suspicion. The experts upon either side; then, being equally trustworthy, and, so far as the jury can know, equally authoritative, what is to be done when the sworn evidence of the one is directly contradictory of that of the other? Shall the juror, with no special fitness of knowledge or training, attempt to decide the questions at issue? Evidently he can do this more readily without expert testimony than with it; for then, at least, he will not be setting his opinion against that of the specialist presumably better fitted to form an opinion. Shall he ignore the expert testimony altogether, and decide as to the guilt or innocence of the prisoner without reference to the questions involved in the evidence of the experts? Obviously such a course would be most unjust to the prisoner and unfair to society, for the cause of death, for example, must be an important link in the chain of evidence establishing the fact that murder has been committed, and fixing responsibility for the crime upon this or that individual. When the questions in dispute involve a matter of such gravity, one horn or the other of the dilemma must be chosen, if other decision is to be reached than the Scottish verdict—"Not proven." As American practice justly requires the acquittal of an accused person of whose guilt the jury entertains a reasonable doubt, the only right way out of the dilemma is acquittal. Thus justice must often miscarry, for how can a jury fail to have reasonable doubt when equally reliable and directly opposing evidence is offered on both sides?

None of these three methods—decision on technical subjects by an untrained jury, ignorring of the subject-matter of expert testimony, or acquittal because the jury has been befuddled—can be satisfactory. Is there any escape from the difficulty? It has been held—and the secular press has urged this view with some asperity—that the difficulty arises only because each side presents witnesses who are not impartial, but occupy the position of hired advocates: their duty being not to show all the facts in the case, but merely those most advantageous to the side they represent. From this point of view it is contended that the present method of securing expert testimony should be abandoned; that the expert should be an officer of the court, and that it should be his duty to investigate the facts of the case impartially, and present his con-

clusions as a judicial report, to be accepted by the jury without question. This easy solution of the problem, however, ignores the real crux. The medical sciences are not yet exact. It is only upon doubtful matters that conflicting testimony can be offered. In a case so plain that under the plan proposed the report of an official expert could be accepted by both sides unquestioned, it is extremely improbable that, even under present faulty procedure, the most astute lawyer could befog a jury without the aid of a venal witness. When the case is not so plain, the official expert must either report himself in doubt and let the jury decide, or the subject must be ignored, or the doubt must lead to acquittal—the same triad of unsatisfactory possibilities as before; or else the side against which he reports will bring its experts to criticise the report, and the other side will bring experts to uphold the report, and the same conflict of testimony confronts us once more.

On the whole, however, the method of investigation and report by an officer of the court, whose character and attainments and the manner of whose appointment are unexceptionable, has several advantages. His investigation would be deliberate; his report would be thorough and complete; bribery aside—and we are assuming bribery to be impossible—he would have no temptation to favor one side or the other; and in the course of such investigations as examination of organs and chemical analyses the whole process could be watched by a representative of the accused, whose criticisms could be made and met at the time. This plan differs from the practice that prevails in France and Germany, where we believe the accused is not represented at the investigation. The accused, moreover, should still have the right to dispute the correctness of the conclusions of the official expert, and in matters of opinion—for example, as to the significance of certain symptoms—conflicting testimony on both sides must be expected.

The animadversions of some writers in the secular press upon the testimony of medical experts is most unfair and unjust to an honorable body of men. Everyone is entitled to have his case exhibited in the best light possible; and all are agreed that it is better for a guilty man to escape for want of proof than for an innocent man to be unjustly convicted. There is absolutely no means of securing unanimity of opinion upon matters not subject to rigid demonstration; and in the present state of science it is only a minority of the questions arising in medical jurisprudence that are thus subject. A brilliant instance of rigid scientific demonstration was, however, afforded by the testimony of PROFESSOR FLINT in the recent trial of a character known as "Frenchy," and this testimony undoubtedly secured the conviction of the prisoner.

The sages of the Talmud said that "Truth was the child of Disputation." On the whole, the ends of justice are substantially served by getting all the facts and all their opposing bearings upon the record; and as we have shown, the inherent difficulty that cannot be gotten over by any device is simply this, that "doubtful things are mighty unsartain."

AFFAIRS AT THE JEFFERSON MEDICAL COLLEGE.

THE graduates and friends of Jefferson College and of medical eduation will be glad to learn of the success of the trustees in securing for the college a new site, to which it is intended to remove so soon as the proper buildings can be erected. A large area has been secured on South Broad Street, and the committee are now considering questions of construction, plans of buildings, etc.

The splendid record of work done throughout the long period of her history—the great men who have been teachers and pupils within her walls, the living monument of her ten thousand graduates—has placed the name and tradition of Jefferson in every part of our own country, and, indeed, of the civilized world, and has developed an historic momentum that should be utilized and made to serve the highest interests of civilization. In consonance with this history and possibility of usefulness and power, it now behooves her officers and alumni to seize with firm grasp the proffered opportunity of renewed life.

The old methods of institutional usefulness and work have in great part, as we all know, been outgrown, and with new science and civilization has come the need of changed methods of teaching and of research, of enlarged laboratory facilities, the free subdivision of departments, etc. Science is democratic, our nation is democratic, and, in accordance with the demands of this progressive age and of the prevalent sociological spirit, teaching facilities and functions must be multiplied and enlarged, fresh talent welcomed and pressed into service.

It is simply absurd to suppose that any single

man can drill and outfit several hundred students in one of the seven chief branches of medical science. An immense augmentation of the teaching force is demanded to conform to the educational necessities and standards of to-day.

There can be no doubt of the advisability of the endowment of chairs in all medical schools, so that even that suspicion of influence may be avoided which must exist so long as Faculties have a financial reason for receiving the largest possible number of matriculants, and for sending forth the largest possible number of graduates. It is high time we had learned the evident truth, that in medical education quality must be rated far higher than quantity.

It is also very desirable that the new move shall enable Jefferson to lead in the great reform her history has marked out for her—a practical, clinical, bedside method of teaching. All the instruction exclusively didactic and the operations only looked at cannot render the student competent to do the future physician's and surgeon's work. The immense hospital *clientèle* should be utilized for the benefit of the student and his future usefulness. Here is the place for the hundred times multiplied corps of clinical instructors and drillmasters in the routine work of the diagnosis and treatment of common diseases. In the large clinics it is too commonly true that rare cases and curiosities and the "show operations" too exclusively occupy the attention, while the simple every-day diseases—the all-important things for the student—are neglected, and the veriest rudiments and elements of clinical experience are not gained.

To live and grow, the institution of the future must be officered by men of a high ideal and endowed with a large morality. The teaching of the future must be drudgery and work, for the benefit of the student and not of the teacher, with such systematic subdivision and military precision that a hundred harmonious departments shall conspire to produce men knowing how to find disease, knowing it when they see it, and instinct with therapeutic knowledge and power.

PUBLIC TEST-OFFICES.

An important feature of the work to be done at the hygienic laboratory at the University of Michigan, at Ann Arbor, is the examination, at a nominal fee to cover actual expenses, of articles of food and drink, on request of health-officers throughout the State. Such work is already done to a limited extent, but it is proposed hereafter to enlarge its usefulness by making it available to sanitary officers of the State.

The usefulness of such a laboratory could be still further extended by allowing citizens generally the privilege of having tested, at a nominal cost, not only suspected articles of food, but such articles of domestic use as are liable, at times, to contain poisonous substances. For a number of years there has been established in Paris a public test-office, where all articles of food, beverages, etc., are analyzed and tested by experts, who also perform the duties of inspectors of markets and among the tradesmen. For a nominal sum, and in some cases gratuitously, anyone can ascertain the composition of any suspected article of food. Articles of domestic use, clothing, colored toys, wall-papers, etc., are also examined, in order to detect any poisonous ingredients that may be present.

The establishment of a public test-office would excite popular interest and be the means of instructing the people in matters closely connected with their physical well-being. Indifference to causes acting injuriously upon health is rightly attributed to the want of proper knowledge. The chrome-yellow poisoning in this city some years ago would never have reached the proportions it did, had the people been in possession of the knowledge that leads to suspicion.

It is very necessary to have test-offices and inspectors to search for deleterious articles of food or of domestic use, but it is quite as important to secure the coöperation of the public and keep active their interest in measures employed to prevent the sale or use of such articles. The public should be made to assume a share of the responsibility of noting and reporting suspected articles, and in no better way can this be accomplished than by offering free facilities for investigation.

The moral effect of establishing a bureau of investigation would be repressive if not preventive of practices now foisted upon the masses because of their supineness and lack of information. By freely offering the services of experts, the cöoperation of the public would be secured, and as a result greater progress would be made not only in detecting, but also in breaking up harmful practices that are none the less common because they so generally escape notice.

THE FIRST INSTITUTE OF HYGIENE IN THE UNITED STATES.

IN his address delivered at the opening of the Institute of Hygiene of the University of Pennsylvania, and published in THE MEDICAL NEWS of February 27th, DR. BILLINGS stated that "this is the first structure of its kind erected in the United States." In the year 1888 a building was erected for the use of the Hygienic Laboratory of the University of Michigan, at Ann Arbor. According to the official calendar of 1888–89, this building "contained a large room for general work in hygiene, a lecture-room, a microscopical room, separate rooms fitted especially for gas analysis, water analysis, and bacteriological work; a disinfecting chamber, a cold chamber, and three private rooms for original research. The laboratory is furnished with all necessary chemical, optical, and bacteriological apparatus. A full set of KOCH's bacteriological apparatus is in use. The chief purpose of this laboratory is to furnish proper facilities to those who are competent to carry on original investigations in hygiene, and it is open to any such person who desires to pursue special lines of investigation, provided he comply with the requirements for admission to the literary or the medical department of the University." Courses of instruction were given by DR. VAUGHAN and MR. (now DR.) NOVY upon Sanitary Science, Sanitary Examinations, Analytical Chemistry, Original Research on the Causation of Disease, including a Course in Bacteriology. In the friendly competition in the scientific world it is only just that credit and priority be given when due, and it is with the view of correcting any possible misapprehension that the foregoing facts are recorded.

PLAGIARISM EXTRAORDINARY.

THE MEDICAL NEWS presents its compliments to *The Western Medical Reporter*, and to a contributor to its issue of February, 1892—one CHARLES C. KOHNING, M.D., of Brussels, Ill. The editors of *The Reporter* are evidently not such good readers of THE NEWS as their contributor. The latter writes an article presumably original, but which is copied *verbatim* from the article of PROFESSOR GOODELL in THE MEDICAL NEWS of November 29, 1890. DR. GOODELL'S paper was entitled, *What I Have Learned to Unlearn in Gynecology*. Dr. KOHNING omits the word *have* in his title. There is one original sentence in Dr. KOHNING'S article, and that, as so often occurs, proves that the gentleman has also other educational and original qualities: "*As proof of this see American Indian and several other nations.*" A funny typographical blunder completes the evidences of originality. DR. GOODELL spoke of a medieval superstition—the belief in two seeds, the male and female semen, etc. To the medieval ignorance is added the modern, and we have "the existence of hoo-seeds"—with an apt exclamation point!

PROGRESS IN THE UNIVERSITY OF BUFFALO.

WE are glad to learn of the zeal and energy manifested among the officers and friends of the Medical Department of the University of Buffalo. A noble building is being erected, which will be one of the finest and best equipped in the country. At the opening of the next session the three departments of medicine, pharmacy, and dentistry will occupy this new home, and enter with fresh spirit upon what cannot fail to be a new and larger career of usefulness. The medical department has long been recognized as among our best medical schools, with an exceptionally able corps of teachers; and in upholding and leading the movement for a higher standard of medical education, the officers of this institution are to be congratulated and complimented for their success and for the work done, as also encouraged with best good-will toward the realization of further work promised.

SELECTIONS.

THE STATE BOARD OF HEALTH AND THE LABORATORY OF HYGIENE OF THE UNIVERSITY OF PENNSYLVANIA.

AT a regular meeting of the State Board of Health and Vital Statistics of the Commonwealth of Pennsylvania, held November 12 and 13, 1891, a communication was received from the Trustees of this University announcing the early opening of its new Laboratory of Hygiene, and presenting a brief curriculum of the proposed line of instruction; whereupon the following resolutions were adopted:

"*Resolved*, That this Board has received with sincere satisfaction the formal announcement of the approaching opening of the Laboratory of Hygiene of the University of Pennsylvania, considering that this event marks an era in the progress, not of science only, but of civilization, in this State.

"*Resolved*, That the Secretary be instructed to communicate with Dr. William Pepper, Provost of the Uni-

versity, and with Dr. John S. Billings, Director of the Laboratory of Hygiene, suggesting a conference for the purpose of formulating a plan by which this Board may avail itself practically of the facilities to be afforded by the Laboratory for the investigation of disease, and of the means for its prevention, for the analysis of foods, water and other beverages, and for bacteriological studies.

"*Resolved*, That in a definite coöperation between the University and the State Board of Health in the prosecution of such researches this Board recognizes an opportunity not only for mutual aid, but for advantage of the greatest moment to the entire Commonwealth."

In accordance with the foregoing resolutions such a conference has been held, and to me has been assigned the duty of briefly stating the conclusions which were reached, premising, however, that they have not as yet been submitted to the Trustees, and may be, to some extent, modified before either body is called upon to consider them.

The necessity of a Laboratory of Hygiene to the State Board of Health has been urgently felt, and arises out of the duties imposed upon the latter by Section 5 of the Act of Assembly establishing it, which reads as follows:

"The State Board of Health and Vital Statistics shall have the general supervision of the health and lives of the citizens of the Commonwealth, and shall especially study its vital statistics. It shall make sanitary investigations and inquiries respecting the causes of disease, and especially epidemic diseases, including those of domestic animals, the sources of mortality, and the effects of localities, employment, conditions, habits, food, beverages, and medicines on the health of the people. It shall also disseminate information upon these and similar subjects among the people. It shall, when required by the Governor or the Legislature, and at such other times as it deems important, institute sanitary inspections of public institutions or places throughout the State."

Now, to carry out in any adequate degree the purposes of the law with regard to investigating the causes of disease, and the effects of foods, beverages and medicines on the health of the people, two things, among others, are absolutely essential: first, that the Board should have means and opportunities for making or procuring chemical analyses; and, second, that it should have means and opportunities for prosecuting what are now known as bacteriological examinations, the study of the germs of disease. And it goes without saying, that where the interests of the health and lives of five million people are concerned, these means and opportunities should be on a generous scale, and should conform to the most recent developments of scientific hygienic research, both in this country and in Europe. It does not at all meet the intention and requirements of the statute, that the Secretary of the Board should spend a few cents on test-tubes and chemicals or press his old Dolland microscope, handed down from a previous generation, into the service of the State. Nor is it fitting that this great Commonwealth, with its millions of revenue, should be depending, as it has done—I say it with burning cheeks—on the charity of private chemists, who have, in a spirit of generous patriotism, placed their services at the disposal of the Board in order to enable it, in some slight degree, to meet the claims that are constantly and properly made upon it for the analysis of suspected waters and foods. It is hoped, therefore, that the Trustees will see their way clear to allowing the Board to refer applications of this kind to the Laboratory for investigation. The Board, for its part, will make every effort to obtain from the Legislature a reasonable appropriation for such purposes, distinct from its general appropriation, which will enable it to meet at least the cost of all work done for the State. Further, Section 9 of the Act creating the Board instructs it "from time to time to engage suitable persons to render sanitary service or to make or supervise practical and scientific investigations and examinations requiring expert skill, and to prepare plans and reports relative thereto." Observe the phrases, "suitable persons," "expert skill." Heretofore the Board has been compelled to call to its aid for these objects simply medical men—intelligent, educated, sound practitioners, but without that special training and equipment which would render them "suitable persons" in any strict, technical construction of the expression, or would furnish them with "expert skill." Here, again, the laboratory will prove the right hand of the Board, giving just that instruction which a sanitary inspector needs to fit him for his special work. And, on its side, it will be the object of the Board to pursue more persistently, even than it has in the past, its purpose of obtaining a thorough sanitary organization of the State under legislative sanction and compulsion, the result of which will be to create a constantly increasing demand for just such trained practical sanitarians as this school will graduate. In this view of the case it might be the part of wisdom for you, gentlemen, Trustees, to place a certain number of scholarships at the disposal of the Board.—*From the address of Benjamin Lee, A.M., M.D., Ph.D., Secretary of the State Board of Health of Pennsylvania, at the opening of the Laboratory, February 22, 1892.*

WASHED AIR FOR HOSPITALS AND ASSEMBLY ROOMS.

AN ingenious method of purifying and clarifying air intended for ventilation is in practical and continuous operation in the wards of the Victoria Infirmary at Glasgow. The air is renewed six times an hour. Before it enters the wards it is filtered and washed by being passed through an air-washing screen of cords, formed of horsehair and hemp, closely wound over a top rail of wood and under the bottom rail, forming a close screen sixteen feet long by twelve feet high, affording nearly 200 square feet of surface. There is a constant trickling of water over this screen, by which it is kept wet, and the air, in filtering through it, has the dust and soot particles removed; when once these have adhered to the wetted surfaces a current of air of considerable velocity will not carry them through the screen, but the falling water floats them down into the drain. An automatic flushing-tank is fixed in a position whereby twenty gallons of water is instantaneously discharged over the surface of the screen every hour, to remove any accumulation of wetted dust, soot, or germs that may not be removed from the screen by the water trickling over its surface.

This goes on day and night, and in the district where

the infirmary is built—near to the Queen's Park, the atmosphere of which is supposed to be the purest in the city—a very considerable amount of soot particles is extracted by this screen. Indeed, it is stated that a piece of jute Hessian cloth that was placed in the air-current in front of the screen, in six hours became nearly as black as graphite. It is alleged that one of the chief advantages of the screen is the facility with which it removes every vestige of fog; and that during the past winter, when there were many days of fog of great density, within this building, as soon as this screen was passed, the air was beautifully clear and bright. After passing the wet screen the air is warmed by coming into contact with steam-heated coils.

The air enters each ward by wide, shallow ducts, placed along the wall five feet above the floor; the incoming air is directed toward the ceiling and is diffused; it drives out through openings at the floor levels the air that had previously filled the ward. Recent experiments made on the quality of the air taken from three feet above the floor and three feet below the ceiling are stated to have shown that the air at three feet from the ceiling had no organic matter in it, and that the air of the ward generally was almost entirely free from microbes or moulds.—*British Medical Journal*, No. 1622, p. 255.

CORRESPONDENCE.

PRACTICAL METHODS OF SANITARY INSPECTION.

To the Editor of THE MEDICAL NEWS,

SIR: Your recent editorial article on the inspection of dairy cattle calls attention to a very generally overlooked department of State and municipal sanitary work. The dangers of meat and milk from diseased cattle are so evident, that they should no longer give rise to argument, but the question as to what per cent. of our food-supply from this source is affected is one that demands the most earnest attention of all practical sanitarians. I am convinced that quantities of diseased meat and milk are often sold by those who are ignorant of its character and who really believe it to be of the best quality. As an illustration, I may mention that our meat-inspector has more than once found it necessary to condemn meat just received from Kansas City, bearing the stamp of approval of the government inspectors at that point. In some of this "approved" meat abscesses have been found at or near the vertebræ or deeply seated in the loin.

It is most difficult for municipal boards of health to exercise authority in these matters, for if any obstinate shipper chooses to dispute their authority, he can give them an endless amount of trouble. It is indeed fortunate that in very many instances the shippers are anxious to do what is right and to coöperate with local authorities in these inspections. But the interests of a community ought not to depend on the whims or good humor of any interested parties, however honest their intentions, because it is hard to say at what time interest may blind their eyes. State boards of health should exercise jurisdiction over such matters, so that small communities would not be forced to go to the expense of maintaining a system of food-inspection in order to protect themselves against the importation of diseased meats.

The field for the local board of health seems to be broad enough if only home-killed meat and the regular milk-supply of the city are properly inspected. By a wise exercise of the power of issuing licenses to milk-dealers, the city or town may find a way of stretching its authority over the dairies beyond its limits, the milk of which forms part of the city's supply.

In this city we have found such a plan to work well, and the dairyman who will not submit to an inspection of his dairy, barns, cows, and pasture, understands that he runs the risk of having his license revoked, in addition to the added ruination of publication in the daily papers of his refusal, with the reasons therefor.

I enclose copies of the blank forms[1] used for making a record of these dairy-inspections, which are conducted by the meat and milk inspectors together. In addition,

Per cent. of solids Per cent. of water
Adulteration No. of samples taken

we have added to our list of routine questions asked in the sanitary inspection of houses in which any contagious disease has existed, this one of "milk-supply."

During last week the inspectors found it necessary to kill two dairy cows, one for pleuro-pneumonia and the other on account of tuberculosis. In each instance the lungs and omentum were removed and brought to the Health-office, where the diagnosis was confirmed.

In conclusion, every city ought to have a system of inspection of the dairies from which the citizens obtain their milk-supply; the dangers of infected milk are too hideous to be overlooked by any properly conducted Health-office. A little money expended in this work will do an amount of good work that can never be measured by dollars and cents. And if a whole year's work were to give no greater results than those obtained by our inspectors in the one week mentioned, it would still be well worth the money outlay.

Very respectfully, Wm. P. Munn.

Denver, Colorado.

SCARLATINA OR RÖTHELN.

To the Editor of The Medical News,

Sir: In The Medical News of February 13, p. 186, Dr. W. R. Lee reports a number of cases that, by reasoning and exclusion, he considers as scarlatina. I have had a similar experience; the sequelæ were like those in Dr. Lee's cases, except that in four there was evident desquamation. I was in a quandary as to a diagnosis, for the cases were among young and old, and I could trace the spread by contact—visiting neighbors, etc.

In the course of my investigations I found the article of Malcolm Morris on "Rötheln, or German Measles," with the description of which my cases best accorded. There is, however, a good deal of risk attendant upon a diagnosis of Rötheln, with the permission for the patient to come in contact with other persons. It is safer to consider a doubtful case as one of scarlatina, and to isolate it and treat it accordingly.

In one case, in a child, the onset was sudden, with vomiting; the rash was distinct; the strawberry tongue was plain; the glands were swollen, also the uvula, tonsils and posterior walls of the pharynx; the pulse was 140; the temperature 103.6°. On the following morning, however, the pulse was 90, the temperature 99°; the rash was distributed all over the body, except on the neck and face. The redness disappeared on pressure, but at once returned when the pressure was removed. In only one or two of all the cases did the rash appear upon the face.

Morris describes Rötheln as an acute infectious disease, characterized by an eruption of red blotches, slight sore-throat, coryza, and but little constitutional disturbance. If the spots be large, they are generally irregular in shape; if they be small, they are more crowded together and present an appearance more resembling the eruption of scarlatina. He speaks of the rash as appearing on the face, but in my recent cases there was none on the face; although in some similar cases seen four years ago the rash did appear on the face. The rash lasts about two days and then fades away, leaving a slight brown stain that gradually disappears; it is rarely followed by desquamation, and if at all, in minute scales. In my cases, except in those sick before the rash appeared, the rash faded within from forty-eight to seventy-two hours, and the desquamation was scaly. The constitutional symptoms that accompany the appearance of the rash are chiefly those of catarrh, and occur at the same time as the rash appears or precede the rash by less than twelve hours—not by some days, as in measles.

The tongue is coated with white fur, through which a few large papillæ can be seen (our strawberry tongue), more often at the tip than elsewhere (such was the case in my patients). The fauces are somewhat injected and the tonsils may be swollen.

An important symptom is the tendency of the lymphatic glands to become enlarged. This is more constantly the case with the glands of the neck, especially with those situated behind the sterno-mastoid muscles, but the glands of other parts of the body are not always exempt, as two of my patients complained of swellings in the groin, where the lymphatic glands were swollen and tender. The prognosis is favorable. No special treatment is required.

As in many families in this vicinity one or other member has presented the rash without the attendance of a physician, and as I was consulted in only two or three cases, I am inclined to adopt the diagnosis of German measles, or Rötheln.

A. D. Ayer, M.D.

Charlottesville, Indiana.

NEWS ITEMS.

United States Marine-Hospital Service.—A Board of Officers will be convened in Washington, May 2, 1892, for the purpose of examining applicants for admission to the grade of assistant surgeon in the United States Marine-Hospital Service.

Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character.

The following is the usual order of the examination: 1. Physical. 2. Written. 3. Oral. 4. Clinical.

In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate.

The examinations are chiefly in writing and begin with a short autobiography by the candidate. The remainder of the written exercises consists in examination on the various branches of medicine, surgery, and hygiene.

The oral examination includes subjects of preliminary education, history, literature, and the natural sciences.

The clinical examination is conducted at a hospital, and when practicable candidates are required to perform surgical operations on the cadaver.

Successful candidates will be numbered according to their attainments on examination and will be commissioned in the same order, as vacancies occur.

Upon appointment, the young officers are, as a rule, first assigned to duty at one of the large marine hos-

pitals, as at Boston, New York, New Orleans, Chicago, or San Francisco.

After four years of service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon.

Promotion to the grade of surgeon is made according to seniority and after due examination, as vacancies occur in that grade. Assistant surgeons receive sixteen hundred dollars, passed assistant surgeons eighteen hundred dollars, and surgeons twenty-five hundred dollars a year. When quarters are not provided, commutation at the rate of thirty, forty, or fifty dollars a month, according to grade, is allowed.

All grades above that of assistant surgeon receive longevity pay, 10 per centum in addition to the regular salary for every five years' service up to 40 per centum after twenty years' service.

The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. Further information or invitation to appear before the Board of Examiners may be obtained by applying to the Supervising Surgeon-General, Marine Hospital-Service, DR. WALTER WYMAN.

Association of American Physicians.—The annual meeting of the Association of American Physicians will be held May 24, 25, and 26, 1892, in the Medical Museum and Library, Washington, D. C.

The subject selected for discussion is "Dysentery." Dr. William T. Councilman, as referee, will consider the etiology and pathology, and Dr. A. Brayton Ball, as co-referee, the symptomatology, complications, and treatment.

The following members will present papers:

Henry M. Lyman: The President's Address. Charles Carey: The Production of Tubular Breathing in Consolidation and Other Conditions of the Lungs. Samuel C. Chew: (Title to be announced). William C. Dabney: A Contribution to the Study of Hepatic Abscess. I. N. Danforth: Tube Casts and their Diagnostic Value. George M. Garland: The Treatment of Follicular Tonsillitis. Heneage Gibbes: The Morbid Anatomy of Leprosy. Hobart A. Hare: A Collective Investigation in Regard to the Value of Quinine in Malarial Hematuria or Malarial Hemoglobinuria. A. Jacobi: (Title to be announced). W. W. Johnston: Treatment of Acute Dysentery by Antiseptic Colon and Rectal Irrigation. Thomas S. Latimer: Alcoholism. Morris J. Lewis: A Study of the Seasonal Relations of Chorea and Rheumatism for a Period of Fifteen Years. Morris Longstreth: (Title to be announced). Francis T. Miles: A Case presenting the Symptoms of Landry's Paralysis, with Recovery. William Pepper: Report of a Case of Glanders, with Results of Bacteriological Study. T. Mitchell Prudden: (Title to be announced). George M. Sternberg: Practical Results of Bacteriological Researches. Charles G. Stockton: Misconceptions and Misnomers Revealed by Modern Gastric Research. William H. Thomson: The Significance of Intermission in Functional Nervous Diseases. Victor C. Vaughan: Certain Toxicogenic Germs found in Drinking-water. B. F. Westbrook: Studies in Hypnotism. James C. Wilson: Pulsating Pleural Effusions. George Wilkins: The Cold-water Treatment of Typhoid Fever.

The American Medical Association will hold its forty-third annual session at Detroit, Mich., June 7, 8, 9, and 10, 1892. Dr. J. S. Cain, of Nashville, Tenn., will deliver the Address in General Medicine; Dr. John B. Hamilton, of Chicago, Ill., the Address in General Surgery; Dr. Charles A. Lindsley, of New Haven, Conn., the Address in State Medicine. DR. HENRY A. WALKER, of East Detroit, is the Chairman of the Committee of Arrangements.

The International Medical Magazine is the name of a new monthly, edited by Dr. Judson Daland, and published by the J. B. Lippincott Company. The first number bears date of February, 1892. It consists of one hundred and twelve pages of reading-matter, made up of sixty-nine different articles, distributed among seventeen various departments.

Neurologist to Randall's Island Hospital.—At a recent meeting of the New York Board of Commissioners of Public Charities and Correction, Dr. William James Morton was appointed neurologist to the Randall's Island Hospital.

ORIGINAL ARTICLES.

ON THE NATURE AND TREATMENT OF FORMS OF DISEASE CHARACTERIZED BY INDIGESTION, THE PRESENCE OF BILE, URATES, AND URIC ACID IN THE URINE, AND BY NERVOUS SYMPTOMS.[1]

BY W. W. JOHNSTON, M.D.,

PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE, MEDICAL DEPARTMENT OF THE COLUMBIAN UNIVERSITY; CONSULTING PHYSICIAN TO THE GARFIELD AND CHILDREN'S HOSPITALS, WASHINGTON, ETC.

THERE is a group of cases often met with in practice that has a great interest for us, on account of the large number of the associated symptoms, the obscurity of their origin, the differences of opinion as to their nature, and the difficulties encountered in their treatment.

The patients included in the group to which I refer give us histories that are more or less alike in their essential features, although the complaint for which relief is sought may be very different in different cases. It may be that distress after taking food, or obstinate constipation, or loss of flesh and color are the reasons for their applying for treatment; or any one of a very large number of symptoms of functional disorder of the nervous system may have excited their apprehension of the existence of some serious organic disease. These symptoms range all the way from simple headache or vertigo to absolute inability to perform any mental work. The history of the case is generally something like this:[2]

The disorder began many years ago. The patient's life has probably been a sedentary one, or one filled with great care and anxiety; his hours of eating and sleeping have been irregular, and all the influences have been excited that are likely to disturb the working of many parts of this delicately adjusted piece of vital machinery, which was not made to run forever without friction or break, if no attention whatever is paid to the conditions necessary to its perfect working. Among the earlier symptoms were a loss of appetite, a coated tongue, distress after eating, and constipation. These have continued and exist at the present time. The distress after eating includes a sense of fulness or weight in the abdomen, which may begin almost immediately after taking food, but is more marked in from one to two hours, and is accompanied by borborygmi and flatulent distention. The patient is depressed in spirits concerning his health and his inability to work with his former energy and interest. Mental depression may be the most marked symptom presented to us. There is frequently insomnia, but more frequently drowsiness, and a sense of weakness and lassitude or inertia after a meal, and, as a rule, after the midday meal.

There are many other ways in which the nervous system may be implicated. Irritability of temper, hypochondriasis or melancholia, hyperesthesia, paresthesia, or anesthesia may all be seen; pruritus is not uncommon, and there may be urticaria. The other special senses may show some slight disturbances. Suddenly developed symptoms appear, as vertigo, which is sometimes only noticed on turning the head to look behind, or on stooping and rising, and there may be palpitation of the heart and dyspnea.

If the urine is examined it is rarely normal. I have before me now the report of the urinary examination of a patient who had suffered for years with the most obstinate constipation, with other symptoms like those mentioned. The color was amber, the specific gravity 1020, the reaction acid. The urates were in excess; there was no sugar, and no albumin, but there was a large quantity of bile. On microscopic examination there were found many uric acid crystals and amorphous urates. The skin of these patients is almost always pale; the proverbial muddiness may be present.

This brief description will give as good an idea of what is usually found as if I were to give the record of cases, but the following brief histories will perhaps illustrate the association of symptoms most usually found. The first of these is in the words of the patient, who wrote it at my request, and if his description may be thought to include exaggerations or perversions of statement, these exaggerations or perversions of subjective symptoms must be taken as symptoms showing the mental state that is more or less characteristic:

CASE I.—"My age is twenty-five; my occupation is that of a stenographer and typewriter. I have done much mental work; I have not used liquor.

[1] Monthly essay read before the Medical Society of the District of Columbia on November 25, 1891.

[2] All cases are excluded here that at any period in their history show any decided alteration in any organ, as dilatation of the stomach, cirrhosis of the liver, degeneration or other changes in the kidney, etc.

My diet has consisted of condiments, much meat, potatoes, fats, sugar. I have always eaten everything hurriedly, and improperly masticated; I drink much water. I have taken very little exercise. My previous health was good until I was nineteen or twenty years old; then emissions (nocturnal) began —from one or two per week to one in two weeks. There was the gradual development of acne. I was also drowsy in the evening, and unable to keep awake. In November, 1889, I began active stenography and typewriting, and study at night. The acne increased. There was bad digestion, coated tongue continually, thirst after supper, heavy stomach, and great appetite. I always got sleepy about 10 or 11 o'clock in the morning when at work; sometimes, about 2 or 3 o'clock in the afternoon. I also had nasal catarrh. Sometimes I felt well, and at others ill; I was always very sleepy from one to two hours after eating. Nose red and shiny. During the forenoon, while typewriting, my head felt as if it were too full, and I had a sensation of heat about the scrotum and anus.

"Milk and food containing much sugar caused greatest heat and sweating of scrotum. My hands and feet were cold at times, but not moist. I was also more or less constipated. Nocturnal emissions continued; memory became poor. This condition was the same until 1890, when I began to have a feeling of a band around the top of my head after work, and heat of back of neck, oppression in back of head, with occasional headache; drowsiness continued.

"At present (November 22d) I suffer most from bad feelings about my head, from a sense of oppression and drowsiness after eating. My complexion is muddy, and the acne continues, but is not so bad. My hands and feet are cold and clammy on taking exercise. I have a feeling of constriction at the pit of the stomach, and I have also a feeling of pulsation there. I wake up every morning about 4 o'clock.

"In May last, after one month's rest, I felt much better, and have not suffered so much since; I was at that time, and have been since, on light diet, avoiding much beef, all fats, and indigestible food. The emissions have almost stopped. I still have weakness in the knees, and am not inclined to make any effort, mental or physical. The bowels are constipated, the movements small and hard."

CASE II.—Mrs. X. in her early life had been in perfectly good health, but at the age of twenty-five found that she was growing very stout, and devoted herself for some years to persistent dieting to reduce her weight. Her plan consisted of eating almost nothing—one chop and a piece of bread in the day, and some indulgence, as ice-cream, at night. She walked many miles daily, and, in time, had the satisfaction of reducing her weight by many pounds. After this she suffered from a severe nervous shock, and for some years she was much depressed in spirits, and travelled about from place to place. She had always been more or less constipated, but there was a gradual aggravation of this condition, and, at the time of which I speak, the bowels were not moved except by purgatives.

During the winter of 1889–90 her nervous system was extremely irritable; she suffered from the most obstinate urticaria, which, from this time until I saw her first in the winter of 1890–91, continued to be her most troublesome symptom. The slightest pressure of her collar or clothing at any point would produce an immediate outbreak of the rash; at no hour of the day or night was she entirely free from it, and life was, in consequence, a burden. For a short time I tried to benefit the urticaria by using the galvanic current, applying one electrode to the base of the brain and spine, and the other to the periphery, but no good resulted from this; on the contrary, the electricity always provoked an outbreak of the rash.

From the abuses to which her digestive organs had been subjected, her digestion was more or less disturbed, the appetite was capricious, and she suffered after eating. Headaches were also of frequent occurrence, and were connected with constipation and unusual indigestion. There was no loss of flesh and no anemia, but her complexion was never clear, the skin having a yellowish, muddy look. I have three separate analyses of her urine before me as I write. The specific gravity was in the first 1031, in the next 1020, and in the most recent 1014. Urates were in excess in all, and in all but the last uric acid crystals were numerous. Bile was present in varying quantity in the first two, absent in the last. There was no albumin and no sugar.

The treatment was chiefly dietetic; beef, mutton, eggs, ham, etc., being forbidden, and chicken, fish, and oysters advised. Vegetables with excess of starch, and all indigestible foods were excluded; she was advised to masticate her food well. A purgative was given regularly every other night, and pepsin and pancreatin were prescribed after food.

Under this treatment the digestion improved, and she had fewer headaches; the bile disappeared from the urine, and the urticaria lessened, but constipation continued. After a summer's stay in an elevated region, where she lived out in the open air nearly all of the time, she returned to the city. She now has urticaria occasionally only, the bowels are frequently moved spontaneously, and her nervous symptoms are less marked. The diet is still continued.

CASE III.—Mr. F., forty-eight years of age, was a chronic dyspeptic for years as the result of overwork and over-eating. Being rich, he abandoned business, and lived abroad under treatment for some years, and returned to this country five years ago. When he came under my care he was better, but was compelled to live strictly according to rule, to avoid subacute attacks of gastro-intestinal indigestion. He had all the appearances of an intestinal dyspeptic—bad complexion, anemic skin, with flabby muscles and reduced weight; tongue always coated and bowels irregular. He was nervous, irritable, and disposed to hypochondriasis. The urine, on repeated examinations, was found to have a high specific gravity, contained urates in excess, uric acid crystals and bile in considerable quantity. He finds relief only by strict diet, and as the temptation to imprudence is very great in

his life, he has numerous occasions for practising self-control. In this way he is usually comparatively well.

CASE IV.—Mr. S. is an overworked professional man, having had a continued strain on his nervous strength for years. His hours of eating have been very irregular, and he has eaten heartily of nitrogenous foods, using stimulants in moderation. For ten years he has been gaining in flesh and now weighs much more than a man of his size should weigh. Several years ago he consulted me; his urine contained lithates in excess and had a high density. I advised diet and lessened work and called his case "lithemia." He has not followed my advice strictly, and has just been passing through an attack of "lithemic fever," suffering from epigastric and costal pains, loss of appetite, gaseous distention of the abdomen, and constipation. The urine has been loaded with urates, has contained some bile, uric acid crystals, a few fatty casts, and 4 per cent. of albumin. For years his nervous system has been irritable in the highest degree, and he has had a restless, unnatural energy which has been a part of his excess of work.

CASE V.—Mr. C. was a business-man, engaged in work of great anxiety and responsibility. He suffered a great shock in the death of an only son, and after travelling for some months, returned home and devoted himself with renewed and excessive energy to his work. He had always had periodic "bilious attacks" with vomiting, headache, and constipation, but, after the shock referred to, these attacks became more severe and more frequent. His strength began to fail, and finally he was compelled to give up business, and he came to Washington for rest and diversion. I was consulted by him on account of general, obscure bad feelings. I found him thus—nervous, restless, hypochondriacal, complaining of indigestion and constipation. The urine, examined on several occasions, always contained urates and uric acid in excess, bile in quantity, and had a high density. The slightest illness of any sort caused great prostration (subjective) and compelled him to remain in bed for some days, from inability to take enough food to cause a rapid return of strength. Constipation was always marked at these times. Under the effect of a restricted diet, out-of-door life, and rest from work, he gained strength and appetite, the digestion improved, and the condition of the urine changed for the better. But the susceptibility of the nervous system and the digestive system to disturbances from slight causes continues up to the present time.

CASE VI.—Mrs. G., aged fifty-eight years, was always a strong and healthy woman, with the exception of occasional subacute rheumatic attacks, involving the muscles chiefly. For this she has gone every summer to the Warm Springs of Virginia and has returned home improved. In June last she had an attack of subacute gastro-intestinal catarrh, which confined her to her room for a week. The urine then had a density of 1030, contained an excess of urates and uric acid, a large quantity of bile, and a trace of albumin. During the summer, under a strict diet and aids to digestion, she was able to eat more, but she continued to lose flesh, remained anemic, and was constipated, nervous, and depressed.

In September the urine was almost normal, containing only a trace of bile and her general symptoms were better, but she had gained no flesh and was still anemic. At the present time the urine contains bile, but is otherwise normal. She feels stronger, better, has a good appetite and better color, but has, as yet, gained no flesh. The nervous system has never been much disturbed. She has been depressed about her condition, but that is all.

These cases, and others like them, may be divided into two classes, both having associated digestional and nervous symptoms, but in one the nervous, and in the other the gastro-intestinal and hepatic disorder is more prominent. It is not difficult to recognize the symptoms and to associate them with the organs with which they are connected. In a general way we know that digestion and nutrition are out of order, that the secretion of urine is abnormal, and that the nervous system is deranged, but it is not so easy to give a *name* to the affection or to decide as to the seat of the primary disorder.

What is the nature of the affection? Is it to be found described in text-books? I think in this case, as in many others, we will find that everyday experience with disease does not always conform to the clear-cut teachings of the text-book, and that we cannot always label our cases as satisfactorily as we would like. In other words, human beings have a way of being ill through and through sometimes; they associate their symptoms in such a complex way, that we are not able to call their maladies by any one name or even by any compound name. In cases such as those described, no one name can be given to the condition which might not be replaced by some other name equally applicable. Personal bias will lead to a varied choice of terms; functional disease of the liver, intestinal indigestion, catarrh of the small intestine, colon catarrh, constipation, neurasthenia, lithemia, chronic dyspepsia, atonic dyspepsia, anemia, and hypochondriasis are names used with more or less claim to correctness. Each is correct in so far as it points to some striking feature, but it does not explain or express its relationship to other associated symptoms. The problem is to find out what is the *pathologic basis upon which the symptoms rest* and what is the sequence of events in their history.

Two theories can be suggested, between which it is difficult to choose, since both offer a rational explanation of the mode of origin and symptoms, the one placing the initial disturbance in the digestive system, the other in the nervous system. According to the first, the earliest etiologic influence

was in the patient's irregular habits of eating, his hurried meals and imperfect mastication; these made gastric digestion less perfect, and the acid mass passing through the pylorus was in a less perfectly digested state than it should have been.

Incompleted gastric digestion always involves fermentation; hence the duodenum is made to receive, in place of the soft, acid chyme, a mass containing much unaltered or partly altered nitrogenous matter, along with starches and fats, the whole in a state of fermentation, and bacterial multiplication. The task thus imposed upon the intestine is beyond its power to perform; its own work and the stomach's unfinished work must be done, and decomposition must be stopped. Up to a certain point the pancreatic and intestinal juices and the antiseptic bile are able to meet the demand, but sooner or later the time comes when the digestion of fats, starches, and albuminoid matters in the intestines is delayed or incomplete; decomposition must follow, with resulting formation of organic alkaloids. The liver function is deranged, for bile and urates in excess appear in the urine. These conditions are sufficient to explain many of the symptoms, such as distress, flatulent distention, and borborygmi beginning from one to two hours after eating, constipation and the loss of weight and of strength, because absorption and nutrition must suffer along with digestion.

There yet remains one important feature of these cases to be included in this explanation, namely, the disturbances in the nervous system.

It is well known that microörganisms exist in great numbers in the normal intestine; they are derived from food or water. Their multiplication is attended by the decomposition in the intestine and by the development of toxic products which, in health, do no harm, as they are eliminated in the stools and the urine, or are all destroyed in the liver (Bouchard). The putrefactive processes that develop toxic substances are quite distinct from the digestive processes caused by the action of the ferments of the gastric and intestinal juices.

So soon as the peptones pass from the stomach into the intestines they undergo changes that result in the development of ptomaïnes and leucomaïnes. Gastric juice outside of the body brought in contact with fibrin and then subjected to the action of amylic and butylic alcohol, produces an amorphous alkaloid that kills frogs in doses of from five to ten centigrams, and hares in the dose of one gram.

Indol may be taken as a type of a poisonous alkaloid formed by putrefaction, and constantly found in the intestine. It is formed by the decomposition of tyrosin, which is produced by the action of the trypsin of the pancreatic secretion on peptone. Thus the intimate result of normal digestion is fermentative decomposition, with the development of a poison. Phenol and skatol are also due to intestinal putrefaction, and stercorin and excretin result from bile decomposition. In health, as I said, poisons are eliminated before they can do harm, but if any changes occur that delay digestive activity, fermentative processes are increased and the intestine becomes filled with a greatly increased number of microörganisms and a correspondingly greater amount of toxic material. Under these circumstances elimination does not free the intestines sufficiently, absorption takes place, and the system becomes infected by the alkaloids of decomposition. Constipation, by delaying the chief means of escape, undoubtedly favors decomposition and absorption, and is a potent factor in disease.

Brunton has shown that the liver stands at the gateway, receives these absorbed poisons into its substance, destroys some of them (as nicotine), removes others from the blood in the manufacture of bile, and forces them back with the bile into the intestinal canal. Here, if they are not expelled, they are reabsorbed, to pass again into the blood through the liver, and to reënter the intestines, and thus the round is continued without the entrance of the poison into the general circulation. If this last should occur, from excess of poison-production or from the failure of the liver to perform its work, general infection would result. Ludwig and Schmidt-Mulheim have found that the blood ceases to coagulate and the circulation is greatly depressed by injecting peptones directly into the general circulation.

Now the point to which I wish to bring these remarks just made is that, given this intestinal decomposition and absorption of toxines, there is a reasonable probability that the resulting infection of the organisms will lead to reactions everywhere, but particularly in the nervous system, and that the hypochondriasis, mental inertia, irritability, and unrest that characterize these cases are the direct results of this infection.

Acute indigestion is sometimes attended with alarming symptoms, resembling those of acute poisoning. The faintness, intermittent pulse, and languor, of which, after eating, dyspeptics complain, may all be due to the action of these poisons on the nerve-centers. Few men have not suffered at some time in their lives from that loss of energy and drowsiness that follow their hurried meals, and we have all many times seen this symptom occur in connection with well-defined intestinal indigestion. The ordinary explanation of mechanical distention and local pressure will not explain these symptoms. The fact that they follow a small meal as well as a large one, and that they entirely disappear when the digestion improves, is a sufficient proof of their

dependence upon fermentative indigestion in the intestines. Headache, giddiness, sleeplessness, sudden loss of consciousness, convulsions in children, have always been thought to be reflex in nature when accompanying indigestion; but it seems in the light of our present knowledge, that they are much more probably due to the presence in the blood of absorbed and non-eliminated poisons that immediately affect the nerve-centers. These symptoms resemble very much the effects of well-known poisons, as curare, for example, and from the suddenness of their onset and quick relief, their relationship to the time of eating, and absence at other times, it seems as if during digestion poisons were sometimes generated in overwhelming doses.

In lithemia there is a close association of nervous symptoms with the presence of urates in the urine. Mental depression can be expected if the urate deposit is large, while with a clear and abundant urine the mind is bright and hopeful. While we do not know what is the precise cause of this excess, we do know that it is always aggravated by an excess of nitrogenous food, the result of overtaxing an enfeebled duodenal digestion.

It is thought that the liver is more closely connected with the formation of urea than any other organ, and that disturbed function in this organ will lead to excess of uric acid and urates in the blood; and it may be that it is this same disturbed hepatic function that prevents the destruction of absorbed intestinal poisons. There is certainly a very close relationship between nervous symptoms in the cases described, and the excess of bile, urates, and uric acid in the urine.[1]

A recent writer[2] attributes some cases of insanity to absorption of toxic agents developed in the course of gastro-intestinal and hepatic disorders, especially gastro-intestinal catarrh. He refers to his asylum experience as showing that he has averted an impending aggravation of symptoms in mild cases of insanity by a brisk mercurial, followed by a few doses of compound jalap powder, and he refers to a suggestive case reported by Willoughby,[3] "in which acute maniacal symptoms, occurring in a man about fifty years of age, were promptly controlled and his reason restored within twelve hours by copious diaphoresis from a hypodermatic injection of pilocarpine." It was assumed that the elimination of a poison by sweating averted danger.

The question of the continuous production of toxic substances in the intestinal canal in health, and the protection of the organism by physiologic elimination, as well as the auto-intoxication of the organism by the absorption of poisons in alterations of the functions of the gastro-intestinal tract, was developed in detail by Professors Albertoni and Silvia at the meeting of the fourth Italian Congress of Internal Medicine held in Rome. Prof. Silvia enumerates the following substances as probable poisons: peptoxine, organic bases (ptomaïnes and leucomaïnes), indol, phenol, lactic acid, ammonia, sulphuretted hydrogen, acetone, etc.

The direct proof of the fact that the nervous phenomena in such cases are due to the absorption of toxic matters from the intestine is not yet found, but the argument in favor of the theory is a forcible one. The existence of indigestion is known by the symptoms; the presence of toxic matters in the intestines in health is proved; fermentation and decomposition constitute the source of this class of substances, and the greater the decomposition (as in indigestion), the greater is their number and amount. In disease, this excess is shown by finding in the urine sulphuric acid, phenol, indican (resulting from transformation of indol), acetone, ammonia, diamine, the alkaloids, and peptones. The relationship of acute indigestion and nervous disturbances, and the association of fermentative dyspepsia with nervous symptoms and an excess of these products in the urine and feces, give sufficient grounds for adopting this theory as reasonable.

The second theory, which is a plausible one, is that the original cause is in a fatigued or overstrained nervous system; that a disordered nervous apparatus does not regulate the functions of the body, and that through the disturbed vasomotor and sympathetic functions the digestive secretions are deficient or altered in quality; hence result indigestion, intestinal catarrh, and all the symptoms of innutrition.

It is primarily, then, according to this view, a neurasthenia—that is, there is an atonic, enfeebled nervous system that does not control and coördinate the functions under its control; with this starting-point we can predict any functional derangement anywhere. The many symptoms connected with the nervous system, their very early development and prominence, go far to support this view, and it is this explanation that is most frequently accepted in these cases. But the difference between the two theories is more apparent than real, and both may be true. I can understand how at one time the overstrained nervous system is the more readily disturbed by the toxic influence, due to indigestion,

[1] In the latest communication on the subject of urea-formation by the liver, the authors do not dispute the idea that the liver produces urea or that there is more urea in the hepatic than in the portal vein; but they do not believe that the liver is the sole or the principal urea-producing organ. They admit that in states of excitation or hyperemia of the liver the production of urea is exaggerated, but think the urea may arise in a process of disassimilation of all the tissues of the body.—*Boston Medical and Surgical Journal.*

[2] Ayres: THE MEDICAL NEWS, July 4, 1891, p. 1.

[3] London Lancet, No. 21, vol. i, 1889, p. 1030.

which exhaustion of the nervous system has helped to bring about, and, again, how nervous symptoms may be due to general infection by absorbed poisons alone; or it may be that there is a double origin, and that the total is not complete until the digestion and nerve-supply and associated functions are involved.

In the present state of our knowledge, I do not see how any more definite view can be reached. We have advanced to the point of understanding the danger of indigestion and constipation, the existence and probable absorption of toxic matters in the intestine, the close connection of the liver with these conditions and with the urinary changes, and from this knowledge we gain important indications as to treatment; but beyond this it does not seem possible to go at the present time.

Treatment.—No treatment can be successful in cases like these which does not result from a survey of the whole field of disorder. It is a case in which comprehensiveness of vision rather than minuteness of observation is necessary—the sort of visual power that comes from a knowledge of the physiology of all the functions and their individual and combined variations.

Exactly the opposite mental state is developed in specialism, as seems to me needed for studying and treating these cases. Here the organ studied —larynx, eye, uterus, or nerve-center—is made the starting-point of observation and comparison, and all associated phenomena revolve round a central axis, but the interdependence of organs and functions, and the relative influence of each in bringing about the result, is not easily grasped by any one person, but still less by the too special student.

In this case, whatever may be the starting-point, whichever is the pathogenic theory most worthy of adoption, the plan of treatment involves a restoration of the altered functions of the digestive and nervous systems to their normal state by improved blood-supply, and a higher and better nutrition of all the tissues.

Digestion is not perfect from defective and deficient secretion of digestive juices that are insufficient and defective from altered blood-supply. Again, the blood is altered in quantity and quality from imperfect digestion, intestinal decomposition, and deficient or altered blood pabulum. In this vicious circle it makes no difference where the coil begins. "All roads lead to Rome," and treatment must travel simultaneously over all roads and by-paths toward cure. A combined and harmonious plan directed to attaining the one object—cure—is almost sure in the end to be successful, while any method that, while benefiting one organ and function, overlooks the condition of other correlated disturbances, is unwise and useless. The patient's confidence must first be won, and a close relation must be established between him and his physician. Next, the surroundings must be made as congenial as possible, and anything that can make him hopeful and happy must be supplied.

The prophylactic treatment, of course, includes the avoidance of all causes that overstrain or disturb the functions of digestion and the nervous system. I need not detail in what way the brain and nerves should be kept in the highest state of efficiency by avoiding overwork, and by being spared over-anxiety and worry, and by diversity and diversion in travel. These rules are clear enough; the only difficulty is in carrying them out.

In regard to diet, the lesson must be taught that "what is one man's meat is another man's poison," and that a well man should be fed according to his needs and capacity. Although science is employed in the feeding of other animals, and the law is recognized that for the thoroughbred, the hackney, and the draught-horse the diet should be different, in order to develop and retain the highest capacities of each in speed, endurance, and strength, yet in the case of man, except in athletic training, no law is taught or obeyed. The judge, the clerk, the tailor, the laborer, each requires a different regimen suited to his special needs and habits; in eating, each man should be guided by his hereditary peculiarities, and by his congenital or acquired defects in digestion, and at certain periods in a man's life the food-list should be altered. If we wish to get the highest efficiency from a man in his intellectual or physical life, and to avoid that inevitable breakdown that comes sooner or later to every man who does not regulate his diet according to his age, habits as to exercise, mental work, and digestive activities, we must adapt his food to these conditions. How many men with a gouty tendency live on a gout-inducing diet? How many who need nitrogenous food live on starch and sugar? Medical science and authority should speak on this subject, and instruct a very ignorant and careless world.

The curative treatment must be based upon the fact that intestinal digestion is relatively less perfect than gastric digestion; that the liver must not be overcharged with the results of nitrogenous excess; that fermentation in the intestines must be avoided or relieved, and that prolonged retention of waste matters does harm. Hence the diet should consist of the lighter and more digestible forms of albuminoid food. The temptation is to the reverse of this, and to meet weakness by increasing meat diet and giving raw beef, beef-tea, etc. But beef, mutton, and eggs should be avoided as far as possible, and fresh or salt fish (which recent observation has shown

to be more digestible than fresh fish), oysters, sweetbreads, the white meat of chicken, turkey, and game are to be advised. In regard to vegetables, those that contain the least amount of starch are the best. Lettuce, celery, spinach, onions, raw tomatoes are to be preferred to potatoes, rice, or macaroni. Bread is to be limited in quantity. All farinaceous foods, as oatmeal, grits, granum, tapioca, corn-starch, are bad because they are chiefly digested in the intestine. Fruits, orange juice, grapes, baked apples are agreeable, and not harmful. Gelatin preparations can be given for the same reason.

In regard to milk, there is no definite rule to be laid down; with some it is a typical food; with others it never agrees. But if milk is taken, it should not be used at the regular meals. Being liquid, it is swallowed without appetite, and either its agreeable taste or the idea that it is very nutritious and strengthening induces patients to drink it in considerable quantity. Thus, a supplemental liquid food that is not needed, and that requires digestion, is put into the stomach, increasing its work. Besides, if the digestion is not quickly done, milk easily undergoes fermentation, and this, our most dreaded enemy, enters into action. As a substitute for other foods, as a between-meal food, when only small quantities can be taken at the regular meals, milk, either plain or peptonized, is a valuable addition. Fats are to be cut off when the intestine performs its work imperfectly.

Alcohol in any shape or form is injurious. Sir William Roberts has shown that sherry, claret, port, and hock, in the small proportions of 1 per cent., have been found to paralyze saliva almost completely. While brandy or whiskey do not retard gastric digestion, wines do, and to an extent out of proportion to the small amount of alcohol contained in them. The same is true of malt liquors. But what has a more important bearing on the subject of this paper is the effect of alcohol on pancreatic (intestinal) digestion. In regard to the effect of wines and beer on the digestion of starch, it is found that their retarding influence is entirely due to their acidity, and that as this is neutralized by the bile entering the duodenum, wines are without injurious influence on starch-digestion. Tryptic digestion is only delayed by alcohol in high dosage; in the quantities and proportions in which alcohol is usually taken at meal-time, the absorption of alcohol by the stomach is so rapid that but a small quantity would reach the duodenum, and hence but little injury would follow its use.

There are two serious objections, however, to the use of alcohol in any form and in any quantity in intestinal indigestion; one is that with alcoholic local and general stimulation, more food, especially proteid food, is taken than there is need for; the second objection is that alcohol stimulates cardiac action, induces rapid portal circulation and hepatic congestion, diminishes the resistance of liver parenchyma, and brings about the serious results of interstitial change.

According to Roberts, coffee has less inhibitory effect on salivary digestion than tea, which is a powerful retarder of salivary digestion, on account of the large proportion of tannin that it contains. Both tea and coffee delay stomach digestion, but they have no effect whatever on pancreatic digestion. Hence, it may be concluded that the morning cup of coffee, not too strongly infused, may be permitted to one who is accustomed to it, or that weak tea is not hurtful, and is to be preferred as a drink to hot water, both on account of its pleasanter taste and slightly stimulating effect.

The effervescent table-waters rather aid than delay digestion, and if wines are taken the waters neutralize some of the injurious effects of wines, especially as regard their effect on the digestion of starch.

While the various aids to digestion often fail to secure positive results, yet they should be given. As our object is principally to aid pancreatic digestion, we are concerned more with the methods that bring this about. The objections to giving pancreatin after a meal are so obvious that few have much faith in its efficacy; even a short stay in the stomach on its way to the duodenum will expose it to the action of the acid of the gastric juice, and its activity as a ferment be destroyed. Roberts has suggested a plan for giving it that obviates these objections; his method is to add pancreatic extract to food fifteen or twenty minutes before it is eaten. "Certain dishes, as farinaceous gruels, milk, bread and milk, milk flavored with tea or coffee, or cocoa and soups strengthened with farinaceous matters or with milk, are suitable for this mode of treatment. A teaspoonful or two of the liquor pancreaticus should be stirred up with the warm food as soon as it comes to the table; and such is the activity of the preparation that even as the invalid is engaged in eating, . . . a change comes over the contents of the cup or basin, the gruel becomes thinner, the milk alters a shade in color, or perhaps curdles softly, and the pieces of bread soften. The transformation thus begun goes on for a time in the stomach, and we may believe that before the gastric acid puts a stop to the process, the work of digestion is already far advanced."[1] This method, if successful, would remove, in part, the objections that I have urged to the use of farinaceous foods. In feeble or delayed gastric digestion, pepsin and dilute hydrochloric acid, given after food, must always constitute one of our resources.

All these rules are intended to prevent decompo-

[1] Roberts: Digestion and Diet, 1891, p. 217.

sition and the development of toxic agents in the intestines, but for some time, at least, the evil will continue, and means must be used to render those products harmless, and to eliminate them. The first object is reached by disinfection of the gastro-intestinal canal by means of thymol, salol, naphthol, salicylate of bismuth, etc., the drug to be given before eating, but not within one hour and a half after. Theoretically this is the right treatment, but how far we succeed in carrying it out is a matter of doubt, as the drug has to pass unaltered through the stomach and pylorus into the duodenum.

Elimination is practised by avoiding delay in the intestine and favoring the daily evacuation of the colon. The practice is certainly an old one, and the guide to it has been the reiterated statements of patients that without the daily evacuation bad feelings were inevitable; and they continued to believe this notwithstanding our assertion that moderate constipation did no harm, and that purgatives did a good deal. Now it looks as if they were right, and we were wrong. Delay anywhere in the large intestines means the opportunity for continuing decomposition and absorption of matters unfit for nutrition or injurious to the system. Means, therefore, that favor a rapid transit from cecum to rectum, and that cause the rectum to be emptied daily, must be employed. Cathartics are the last remedies to be advised if the result can be brought about in any other way; a proper diet, change in the habits of life, exercise, and colon massage may accomplish this. If they do not, a small enema of cool water containing some antiseptic, or a mild laxative pill will have to be given. In the choice of a laxative, it does not make much difference what one is selected. Hydragogue cathartics, as Hunyadi and other mineral waters, and drastics, are wrong in every way. A "peristaltic persuader" is best, and the minimum dose that will produce the effect is the one to be prescribed. Electricity has been employed, and is highly recommended; it is used as an excitant to muscular action, and, if properly given, in accordance with the laws of electrical action, it may render great service.

When the toxic products have entered the system, their elimination is favored by diaphoresis, diuresis, and by the inhalation of compressed air or oxygen. Hence arise the benefits of exercise or bathing, friction and general massage, the free drinking of pure water, as Poland water, or some harmless mineral water, as the Lithia waters, the virtues of which depend, in very small part, upon the mineral matters that they contain. In case of muddy skin, with acne, sluggish circulation, cold hands and feet, when there is constipation and a urine dense and loaded with urates and with increased urea, oxygen inhalations would promise a great deal of benefit.

In regard to other drugs, tonics are bad; iron is the worst, and only in those forms in which anemia does not disappear with the improvement in digestion should the more assimilable and least irritating forms be given, as the lactate and pyrophosphate. Bitter tonics are inadvisable; the most they can do is to stimulate the gastric mucous membrane, increase secretion, and it is questionable whether more harm than good is not done by trying to bring this about. Cod-liver oil is objectionable, for the reasons given, and yet in just such cases it is frequently given on "general principles."

The attempt has been made in this paper to discuss the nature and cause of symptoms that we are constantly meeting in our daily practice, and that when we attempt to cure them prove so troublesome to us. There may be many different opinions formed when such a case presents itself for examination, but a comprehensive study of *all* of the symptoms, and an effort to look upon them as closely related and as together forming *one* disease, will help one to arrive at a rational view as to the treatment that should be pursued.

Intestinal chemistry points out to us a probable cause of most of the symptoms, and gives indications for treatment that are of the highest value. But I do not believe that there is any name hitherto applied to this diseased state that expresses the nature, or that is comprehensive enough to include in its meaning its essential features; for while toxemia, lithemia, intestinal indigestion, constipation, functional diseases of the liver, neurasthenia, hypochondriasis, may all be present in any one case, there is not one of these terms that is satisfactory or acceptable. .

A FURTHER REPORT ON THE TREATMENT OF TUBERCULOSIS BY IODOFORM INUNCTIONS.

BY LAWRENCE F. FLICK, M D.,
OF PHILADELPHIA.

IN a paper read before the Philadelphia County Medical Society on November 12, 1890,[1] I made the statement that I had obtained some striking results in the treatment of tuberculosis by inunctions with a solution of iodoform in oil. On April 22, 1891, I presented to the Philadelphia County Medical Society a number of cases treated by this method, and gave a detailed account of some others.[2] As it is now nearly two years since I first began experimenting with this method of treatment, I not only feel justified in making a further report on it, but

[1] This paper was published in THE MEDICAL NEWS of November 15, 1890, and in the Transactions of the Philadelphia County Medical Society for the year 1890.

[2] This paper appears in the Transactions of the Philadelphia County Medical Society for 1891.

in a measure feel obligated to give the profession my more mature experience with it.

Before saying anything as to whether my first conclusions have been borne out by further experience, I will give a short synopsis of the cases I then reported, together with an account of them up to date, and will relate a few cases that I have treated by the method since :

CASE I.—Female, twenty-six years of age. At the time of last report she had had tuberculosis about two years ; had been under treatment with iodoform inunctions about six months ; was almost entirely well, having still a slight impairment of resonance over the right apex, and was gaining flesh at the rate of a pound a week. The case continued to do well, and all symptoms of tuberculosis disappeared. Later on she had an acute attack of insanity, from which she likewise recovered. I have not seen her recently, but a member of her family has informed me that she is entirely well.

CASE II.—Boy, twelve years of age. At the time of last report he had shown symptoms of tuberculosis for about nine months ; had been under treatment with iodoform inunctions about six months, and was to all appearances entirely well. I have seen the boy within a few days, and he continues to be entirely well, although since last report he has had a hemorrhage, and has had to resume the treatment. He is now using the treatment at intervals as a precautionary measure, as he is very much exposed to reinfection, there being two other cases in his family.

CASE III.—Sister of Case II. ; twenty-four years of age. At the time of last report she had been tuberculous about a year ; was in the third stage of the disease ; had been under treatment with iodoform inunctions and internal use of creasote in large doses for about six months or more, and was at the time of report suffering a relapse, after having been nearly well. This case is at present in comparatively good condition ; the disease for the time being is arrested, although she has gone through one or two severe exacerbations since last report. She has given up all treatment except the iodoform inunctions, which she practises faithfully every day. She is now performing the duties of housekeeper for her three brothers, all of whom have been or are now tuberculous. She coughs very little, eats well, looks well, but inasmuch as she has cavities, she may at any time reinoculate herself, and may have an extension of the disease.

CASE IV.—Male, twenty-three years of age. At the time of last report he had been tuberculous about a year; had made great progress toward recovery under iodoform inunctions and large doses of creasote internally; had gained about twenty pounds in weight; was laboring under a recrudescence of the disease, started up by an attack of influenza. He again recovered from the acute symptoms, and promised fair to do well, when in November, 1891, while out driving, he was taken with a severe hemorrhage, which was repeated a number of times, and from which he died in a few days.

CASE V.—Male, twenty-four years of age. At time of report had been tuberculous about two years ; was in the third stage of the disease ; had improved very much under treatment by inunction and large doses of creasote internally ; had gained thirteen pounds in weight, and was enjoying comparatively good health. This case gave up treatment, and has not been under my care since.

CASE VI.—Male, twenty-six years of age. At time of last report had been tuberculous about five years ; was in the third stage of the disease ; had improved very much under treatment by inunctions of iodoform and the use of large doses of creasote internally ; was in bed at the time with acute symptoms which had apparently been precipitated by a trip to Florida. This case continued to grow worse, and died in September, 1891.

CASE VII.—Female, twenty-two years of age. At time of last report had been tuberculous about two years ; was in the third stage of the disease ; had much improved under the treatment by inunctions and the use of creasote internally ; had gained twenty pounds in weight ; was at the time suffering from a recrudescence of the disease, which had been set up by an attack of influenza, and was in a bad condition. This case grew rapidly worse, and died shortly afterward.

CASE VIII.—Male, thirty years of age. At the time of last report had had tuberculosis for about four years ; was in the third stage of the disease ; had cavities in both lungs ; had been under treatment with iodoform inunctions and the use of large doses of creasote internally for about six months ; had had the disease arrested, and had gained much in weight ; was coughing very little, and was rapidly gaining strength. This case continued to do well, and gained so much in health and strength that he, on his own responsibility, decided to go to Denver to start in business. During the first few days of his stay in Denver, whilst working hard to get started in business, he had a hemorrhage, from which he died.

CASE IX.—Female, twenty-three years of age. Had been tuberculous about three months ; was in the first stage ; at the time of last report had been under treatment with inunctions of iodoform for about two months ; was much improved, and had gained six pounds in weight. This case got entirely well, and is well at the present time. She has been and is now engaged in housekeeping.

CASE X.—Male, fifty-five years of age. At the time of last report had been tuberculous about six or eight months ; had been under treatment with inunctions of iodoform two months ; had gained four pounds in weight, and was in fairly good condition. This case continued to do well, but subsequently disappeared from observation.

Some of the new cases that I have treated by thi method are as follows :

CASE XI.—Male, twenty-five years of age ; in good circumstances, a cigar-dealer. Has been tuberculous about two years. Is physically a well-developed man ; father and mother are living and well. For

some years has been much in the company of a young lady who was consumptive, and who has recently died. Began treatment with iodoform inunctions in the latter part of 1890, but when somewhat better discontinued it. Again began the inunctions in April, 1891, and continued them until all symptoms disappeared. At present is following his business, and to all appearances is well.

CASE XII.—Female, eighteen years of age; a store-girl, living comfortably; came to me first for treatment in March, 1891. At that time had enlarged lymphatic glands of the neck, which had been enlarging for about three months; was coughing a good deal, had been losing flesh rapidly for some time, had a pulse of 104, and a temperature of 99⅕°, and had impairment of resonance over the right apex. I put her on iodoform inunctions, had her rub an ointment of iodide of lead into the enlarged glands, and gave her tonics internally. She rapidly improved, and after two months' treatment the glands had materially diminished in size, her temperature was normal, pulse was 76, lung had cleared up, cough had disappeared, and her general condition was good. The girl is at present following her usual avocation, apparently well.

CASE XIII.—Male, about twenty-five years of age; came to me for treatment in the latter part of June, 1891. Had then been in bad health three or four years, had had a cough for a year or more, had had syphilis two years previously, had had what he termed pneumonia six months before, at which time he spat blood, and was generally in a very bad condition. His temperature was 101⅖°, and his pulse 108. There was increased expiratory murmur over the entire right lung and over the upper part of left. There were spots of dulness over both lungs. He had lost about twenty-five pounds in weight. I put him on inunctions of iodoform and gave him a tonic internally. Upon learning his condition he concluded to go South, where his people lived, and I have not seen him since. On December 10, 1891, six months afterward, I received a letter from him, in which he wrote: "Dear Sir: About the 1st of last July you prescribed an ointment for me to rub with, which had oil and iodoform for some of its ingredients. I was suffering at the time from pulmonary troubles. It benefited me a great deal. I have since lost the prescription, and, my lungs giving me again trouble, would like to use it. Please be kind enough to send me a duplicate prescription by return mail, as I am anxious to commence it at once."

CASE XIV.—Female, twenty-seven years of age; a store-girl, in good circumstances, with no history of tuberculosis. Came to me first in the beginning of September, 1891. She had then been sick several months, and had lost twenty pounds in weight. Tuberculous deposit and some breaking down in the right apex. I placed her on tonic treatment and creasote internally, and inunctions of iodoform. She improved very rapidly, at the end of a month had gained about seven pounds in weight, and said she felt like herself again. I did not see her again until January, 1892, when she returned, saying that she had been right well, but that owing to the disagreeable smell of the iodoform she had discontinued the treatment too soon, and that having grown worse she would like to take it up again. She is now rapidly improving under treatment by inunction.

CASE XV.—Female, forty-seven years of age; married; housekeeper, in humble circumstances; came to the out-patient department of the Rush Hospital for Consumption and Allied Diseases, on March 14, 1891. The record there states that her father and one brother had died of consumption; that she had pneumonia two years previously; that she had not felt well since, and that she had been coughing and spitting a good deal recently. Physical examination showed loud, whistling râles, prolonged expiratory murmur over the right apex, and impairment of resonance on the same side above the clavicle in front and above the ridge of the scapula behind. Her pulse was 80, her temperature 98⅘°, her appetite good, tongue large and somewhat coated, heart-sounds normal, throat congested, bowels regular. She stated that she had been losing flesh rapidly. I gave her hydrochloric acid internally, and put her on inunctions of iodoform. She has kept up the inunctions with scarcely any intermission until the present time, and has had practically no other treatment except a tonic. She has gained about eleven pounds in weight, her cough is entirely gone, she has not expectorated for some months, and all physical signs showing an abnormal condition of the lungs have disappeared.

In addition to the cases just related I have treated a number of others by this method, of some of which, however, I did not keep notes; some I was unable to keep under observation long enough to make them of any value; and in a few the diagnosis was so doubtful that I do not feel justified in quoting them. The fifteen cases which I record in this paper, with possibly the exception of Case XV, were, I think, all cases of tuberculosis.

Of the ten cases which I reported before, four have died, three are at present apparently well, one is enjoying comparatively good health, and two have disappeared from under my observation. The four cases that died were all far advanced in the third stage of the disease when the treatment by inunction was begun; all received large doses of creasote in addition to the inunctions; all had done well under the treatment for awhile, having gained from seven to twenty pounds in weight; two died from hemorrhage; in two the recrudescence of the disease was due to influenza. Of the three cases that are at present well, all were in the first stage of the disease, and none had probably advanced beyond this stage. The one case that is now in comfortable condition was in the third stage when the treatment was begun, but had at that time in all probability but little breaking down. The two cases that have disappeared from under my observation were both in the third stage when treatment was begun, were

both doing fairly well, but evidently became discouraged, and went elsewhere.

Of the five new cases here reported, three are in the third stage, and two are probably in the first stage. The two in the first stage are both apparently getting well, although sufficient time has not yet elapsed to determine that. Of the other three cases one promises fairly to recover, as there has been but very little breaking down, and the other two, whilst much better and still improving, will likely follow the course of those reported in my former paper.

As will be evident from the cases here reported, the conclusions reached in my former paper, read before the Philadelphia County Medical Society last April, have been borne out by my further experience. Iodoform will cure tuberculosis in the first stage, and it acts better when administered by inunctions than when given by the mouth. When the disease has advanced to the second or third stage iodoform may do good, but can no longer be depended upon as a curative agent. As I stated in my former paper, creasote should then be given together with iodoform, and given in large doses. If given diluted with hot water, as much as fifteen drops can be taken with comfort. It seems to me, indeed, that creasote is the drug to be relied upon in the second and third stages of the disease. I, however, use the iodoform inunctions in this stage for the reason that the tuberculous nodules in a given case do not all break down at the same time, and that whilst some nodules may be broken down, or have already broken down, there may be many that are still in the first stage.

Along with specific treatment I always use tonics and forced nutrition. Much of the success that I ascribe to specific treatment may of course be due to the tonic and nutrient treatment, but I am bound to say that my results with iodoform inunctions and creasote together with tonic and nutrient treatment are much better than they were before I used the inunctions.

INJURIES OF THE FOOT.[1]

By G. W. CRILE, A.B., M D.,
LECTURER ON PHYSIOLOGY AND MINOR SURGERY, MEDICAL DEPARTMENT OF THE UNIVERSITY OF WOOSTER, CLEVELAND, OHIO.

WHEN the foot is subjected to a traumatism adequate to cause a fracture, there is usually sufficient injury to the soft part to constitute a compound fracture. Viewed from a mechanical standpoint, the foot is a double arch for support and motion, consisting of a few bones held in place by ligaments, and the fascia plantaris, which arises from the os calcis, extending forward into slips and attached to the metatarsal bones and the phalanges.

[1] Read at the Cuyahoga County Medical Society, November 5, 1891.

The integrity of the arch depends upon the integrity of the ligaments and fascia. Mechanically, the foot is a lever of the second class, the tibia the load, the tendo Achillis the power, and the anterior extremity of the arch—the metatarsal bones—the fulcrum. In adjusting artificial feet these simple principles in mechanics are observed.

Fractures of the foot are usually compound, often multiple. The cause is usually a crushing traumatism, as by a heavy piece of iron, powerful machinery, or the wheel of a railway carriage.

The diagnosis, with probably a few exceptions, rests on the usual symptoms of fracture. Frequently there is a "sprain fracture" of the astragalus, which gives no positive symptom of such lesion, and often cannot be detected except upon the operating-table or in the dead-house. I have several times found a comminuted fracture of the head of the second metatarsal bone, when no such fracture was indicated by the ordinary rules of diagnosis. The reason for this exception is apparent when the peculiar position of the bone is taken into consideration. Its head is held as in a vice immovable in a mortised depression, on its internal side, by the internal cuneiform, the posterior by the middle cuneiform, the external by the external cuneiform. Being thus wedged in, when subjected to a traumatism it will break, because its position is uncompromising, receiving the force much augmented by high leverage, thus causing a fracture which without this peculiar mechanical disadvantage would not occur.

When the violence is lateral the tension on the head will be tenfold greater than the force applied, by reason of the propinquity of the fulcrum and the load and the length of the lever. Moreover, this fracture will rarely disclose its presence by crepitus or deformity, even though it be multiple. In making a prognosis of a severe contusion of the anterior part of the foot, the probability of such fracture is to be well borne in mind. Fortunately, the function of this bone is not *per se* important.

Fracture of the toes is readily discovered—the treatment simple, the prognosis good. Even a multiple fracture is promising. I have frequently seen compound comminuted fractures of the toes readily unite. The treatment is simple, and in the event of a compound fracture the result is almost entirely dependent on the success or failure in attainining asepsis. As to splints, none are needed. Each toe should receive a bandage of gauze closely applied, the plantar surface of the toes being packed with antiseptic gauze, until by the ordinary pressure of the bandage the gauze will sufficiently support the fragments. The dorsal surface is likewise padded, so that the plantar and dorsal surfaces at every point will receive an equal pressure. If fracture be compound, the blood that will ooze into the bandage will

materially improve this soft splint. No splint has been devised that yields better results than this method. Unyielding splinting will tend to cause deformity. In fracture of the metatarsals, reduction, closely applied bandage, selective padding, elevation, with ordinary means of combating inflammation, will succeed. If the bones are comminuted and displaced, resection may be performed at any point, regardless of articulations. This, however, will rarely be necessary. Fractures of the tarsus are usually compound and comminuted. Even then there is considerable hope of preserving the foot, especially if the arch is not wholly destroyed. Close bandaging, elevation, rest, antiseptic dressings, are required. Simple plaster-of-Paris bandage is the best. Absolute rest of the foot must be secured, leaving it in the normal position of repose. It is well to bandage the leg, to keep the muscles at rest. The astragalus is most frequently fractured, usually from transmitted violence.

If the fracture be compound, and the fragments cannot be replaced, excision may be practised. I have treated several fractures of the astragalus. In one case a machinist fell some distance, striking on his feet. He was unable to step on his foot, and suffered intense pain. The line of fracture was antero-posterior, the internal fragment being displaced. The fragment was replaced with considerable difficulty by direct pressure with one hand, slowly moving the foot to and fro with the other. There was a tendency to eversion. Adhesive straps were applied over the fragment, and extending three-fourths the circumference of the foot. A pad of gauze was placed over the adhesive, and held in place by a closely applied bandage. A basswood splint was applied to the inner side of the foot to prevent eversion. Inflammation was combated by packing the foot and ankle in ice, and keeping them at rest in an elevated position. The ankle was limited to one-fourth of its normal motion after two months. In four months, by systematic massage and passive motion, more than half of its function was restored. In another case, fracture of the astragalus was caused by a fall from a freight car, striking with the foot upon a steel rail. The fracture was simple, displacement slight, yet the amount of callus thrown out was extensive, causing almost an entire loss of function of the ankle-joint for more than a year. Almost two years have now elapsed; the callus is wearing away with time, and the foot is becoming more useful. In treating fractures of the os calcis, the greatest difficulty presented is to overcome the tendency to displacement by the traction of the tendo Achillis. Although I have never employed it, subcutaneous tenotomy strongly recommends itself as an adjuvant in the maintenance of apposition.

Lacerations and contusions present no features that cannot be treated on general principles. When the foot is lacerated, it has been my custom not to spare soap and brush. After cleansing I immerse the part for five minutes in a bichloride solution. The application of antiseptic dressings, with elevation and rest, insures primary union in the vast majority of cases. Punctured wounds of the sole of the foot often require especial attention, by reason of the tendency of closure of the aperture of entrance of the wounding substance. In my opinion every punctured wound of the foot should, as a routine practice, be amplified by a free incision, and a search made for any foreign substance that may have lodged therein. After irrigating with a strong antiseptic solution, if any further doubt remains as to the asepsis of the wound, I drain it, and apply a moist antiseptic dressing. In any case, at any time, if there arise local elevation of temperature and throbbing pain, free incision must be immediately made. The consequence of neglected or maltreated punctured wounds of the sole of the foot are only too well known to require mention here. There is another class of injuries that often present difficulties. I refer to that class in which some constitutional disease or dyscrasia exists, that presents a culture soil for surgical microörganisms. A slight wound, probably only a contusion, will make a point of least resistance, and a pathologic process far-reaching and disastrous will speedily follow. Constitutional treatment is important. If there is extensive loss of the soft parts a tedious recovery is unnecessary, if the wound is in a healthy condition. In these cases skin-grafting will very rapidly close the wound. I have recently grafted by Thiersch's method with most gratifying results. The patient had suffered a comminution of the bones and the soft parts of his foot by the fall upon it of an iron bucket weighing a ton. The second metatarsal bone and the corresponding toe were amputated. The remainder of the mangled foot was placed in a warm, moist, antiseptic dressing. The integument suffered molecular death, leaving the half of the dorsum of the foot without integumental covering. At the end of two weeks the entire surface was clean. This surface, after cutting away the granulations, was covered with strips of integument taken from the patient's arm in strips about three-fourths of an inch wide and two inches long, their margins being placed in close linear coaptation. The wound was dressed with plain sterilized gauze and absorbent cotton. The dressings were kept warm and moist with a solution of boric acid, and changed in four days. The grafts all grew, and in two weeks the integument transplanted was strong enough to allow the patient to walk about with safety. Where the grafts had been placed there was a depression of half

an inch below the surface of the surrounding skin. This rapidly filled up. During the course of treatment of this wound, with extensive denuded surface, there was no pus nor any pain. I did not find it necessary to anesthetize the patient to cut the grafts, as they were made very thin, scarcely causing capillary hemorrhage. The grafts are said to grow best when transplanted in the same direction on the limb as they were *in situ*.

Consistent with a healthy stump when amputation of the foot is indicated at a point beyond the tarsus, every possible atom should be saved. On the contrary, unless the risks to life are too much augmented when amputation on the proximal side of the tarso-metatarsal articulation is indicated, the whole foot should be sacrificed and amputation of the lower third of the leg be practised, that the unfortunate victim may be duly and truly prepared for an artificial limb.

Manufacturers of artificial limbs are almost unanimous in their disapproval of the tibio-tarsal and tarsal amputations. Experience has taught them that the difficulties encountered in making a useful substitute for a part of the foot are only equalled by the painful disappointment of the unfortunate victim. The mechanical reasons for this difficulty are apparent when we consider the anatomy of the foot.

In all of these operations—Chopart's, Hey's, Lisfranc's, Forbes's, Ligneroille's, Pirogoff's, etc.—you leave a foot that has no value except to carry weight. In the Chopart, Forbes, Hey, or Lisfranc amputations the os calcis remains. The flexor tendons are severed, the extensors remain. There will be a contraction of the gastrocnemius and soleus muscles, with consequent drawing downward of the extremity of the stump, causing pressure on a usually very sensitive cicatrix. In the various other operations, as those of Pirogoff, Le Fort, Guenther, etc., there is insufficient space left for the mechanism of an artificial joint. However, Syme's operation is probably the best that can be performed below the lower third. If the stump can bear pressure, a fairly useful member may be made. All these operations usually leave worse than useless appendages—as an endless source of annoyance to the instrument-maker, torture to the patient, and regrets to the surgeon. The argument of greater mortality against operations on the lower third of the leg has lost weight since the introduction of modern antiseptic surgery. The relative mortality given in statistics is not a fair comparison, as the tables are drawn from an era of surgery in which these operations were performed in preference to the leg operation, so that the cases of this amputation were drawn from injuries much more extensive and serious. I am unwilling to admit that the mortality of operations upon the lower third of the leg, practised on healthy limbs, will be any greater than that of the complicated tarsal and tibio-tarsal amputations.

In amputation of the leg the cicatrix should be made to lie on one side, preferably the posterior side of the stump.

In advocating the abandonment of operations that bear the name of renowned surgeons; that have been taught and practised for generations; and that have occupied a prominent place in the best surgical literature through numerous editions, I wish to remind that the wonderful advances in prothetic science, and the decreased mortality of major amputations through aseptic surgery, are factors that unfortunately were unknown to the older surgeons, else the illustrious name of Chopart would not bring to every surgeon's mind visions of suffering cripples. I fully appreciate that the highest type of surgery is produced by conservative surgeons; but I oppose that conservatism which prevents a patient from obtaining relief from his misfortune by rendering the stump unfit for the application of an artificial limb.

In order to facilitate discussion, I submit the following propositions:

1st. That in open wounds asepsis is attained, if at all, more certainly through the employment of antiseptics.

2d. That unyielding splintings are not indicated in treating fractures of the toes. That the head of the second metatarsal bone is especially liable to suffer comminuted fracture.

3d. That in compound, even comminuted fractures of the tarsus, if in doubt as to the propriety of attempting to save the member, apply moist, warm antiseptic dressings, and await further indications. Suppuration should be the exception, if the case be well managed.

4th. Ordinarily, amputations between the junction of the lower and middle thirds of the leg and the tarso-metatarsal articulation should not be made. At all other points, save all possible.

CLINICAL MEMORANDA.

CAMPHORIC ACID FOR THE NIGHT-SWEATS OF PULMONARY TUBERCULOSIS.

BY JAMES WOOD, M.D.,
OF BROOKLYN, N. Y.,
CLINICAL ASSISTANT IN PATHOLOGY AND PRACTICAL MEDICINE IN THE NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL.

PROBABLY there is nothing so unpleasant or aggravating in tuberculous patients as the profuse sweating that occurs either in the morning or during the entire night. The depression following it does not seem to be due to the sweating itself, but rather to the effects of a

gradual increase in the quantity of carbonic acid gas in the blood, incident to the difficult interchange of gases in consequence of the pulmonary affection. It is well known that in normal respiration the blood does not contain so continuously a high percentage of carbonic acid gas as will cause a less sensitive condition of the centers governing respiration. But in pulmonary tuberculosis, when the energy used in the daily exertions, from excessive coughing or other physical causes, more than exceeds the supply of energy and nutrition that can be furnished by the body, the respiratory centers are greatly depressed, and are not stimulated so quickly by a percentage of carbonic acid gas that normally would affect those centers. The centers presiding over the functions of the sweat-glands, not being affected by the physical causes, respond to the increased stimulation, and pour forth their secretion abundantly. The proper therapeutic mode of combating this functional perversion would seem to be to use such a drug as shall stimulate the respiratory centers, and thereby cause the elimination from the blood of more carbonic acid gas, and in this indirect manner act as an anhidrotic.

Camphoric acid seems to effect this object with less derangement and more satisfactory and lasting results than any other drug. This remedy is best given in doses of twenty grains from four to six hours before the period of sweating is expected. The best method of administration is dry on the tongue, and washed down with a little water. The taste of the drug is not unpleasant; neither does it produce the gastric irritation so frequently experienced with many medicinal agents used under like conditions.

During the last six months I have used it in a large number of cases,[1] with the very best results. That an idea may be had of how it has acted, the following are the brief histories of some of the severe cases in which it has had the most prompt effect.

Case No. 441, a minstrel, twenty-five years of age, had a chancre two years previously. Physical examination demonstrated a well-marked interstitial pneumonia of the larger part of both lungs. His condition was very good. He complained of the usual symptoms of the disease, but had no sweating. The patient grew slowly worse during the next month, at the end of which time the bacilli of tuberculosis were found in the sputum. Exactly one month after the first examination, he was suddenly taken with profuse cold sweatings about 3 A. M. Camphoric acid (20 grains) was ordered and given about 11 P. M. The sweating did not take place the next morning, nor on the day following, but on the third morning it again appeared. The drug was administered every other night, from four to six hours before the expected time of sweating. But three doses were given. From the time of the first sweating symptoms of tuberculosis began to appear. These continued to increase, and were followed by death two months later. One week before death dry pleuritis occurred. No sweating took place after the third dose of camphoric acic, sixty-two days before death, although the patient was greatly emaciated and very weak. The autopsy showed syphilitic thickening of the connective-tissue structures, well-marked pulmonary tuberculosis, and recent pleurisy.

Case No. 709 was a stonecutter, about fifty years of age. The entire right lung was badly affected. Bacilli were found in the sputum in large quantities. Pulmonary disease existed, complicated with tuberculous enlargement of the cervical, axillary, and, in fact, all of the glands on the right side above the diaphragm accessible to examination. These glands grew to enormous dimensions, and were at times painful. The patient's general condition was so very bad that he was placed in the hospital. Under better regimen he greatly improved. In this case the sweating and following depression were marked. Several drugs were tried, but discontinued for different reasons. Camphoric acid controlled the sweating better than any. It had to be continued for several days before a lasting impression was made. The man continued to grow worse, and two months after first seen was taken home, and died shortly afterward. No autopsy was made.

Case No. 446 was a wood-engraver, twenty-one years of age. He presented all the symptoms of pulmonary tuberculosis of some standing. Bacilli were found in the sputum. He complained severely of weakness from profuse sweating. Little benefit was received from the administration of several different drugs for three weeks. Finally, 20 grains of camphoric acid were given. Only two doses were necessary. He had had no recurrence of the sweats for four months afterward.

Case No. 485 was a cigarmaker, thirty-four years of age. There were the physical signs of tuberculous affection of both apices, with the symptoms typical of that condition. Bacilli were found in the sputum. One week after first seeing the patient, he was suddenly seized with an attack of acute diffuse nephritis, which almost resulted in death. In a few weeks he improved, but he still had a chronic affection of the kidneys. He has had several severe attacks of sweating during the last four months. Two doses of camphoric acid were always sufficient to give him relief for at least a week. His condition at the present is very good for one with chronic nephritis and pulmonary tuberculosis.

Case No. 757 was a stonecutter, fifty years of age. In the course of his illness—chronic fibroid "phthisis"—he was troubled for several weeks with profuse sweating, but after giving camphoric acid in slightly increased doses for two nights the sweating did not appear for several weeks.

Case No. 700 was by trade a printer, thirty-nine years of age. This case is similar to No. 441 in having begun as a syphilitic induration of the pulmonary tissues, followed by a chronic tuberculous process. He suffered for several months with recurring periods in which he seemed more prone to severe night-sweats. Treatment, as pursued in the other cases, gave him immediate and lasting relief.

Case No. 704 was a barber, thirty-five years of age. Both apices were affected, and bacilli were found—an undoubted case of pulmonary tuberculosis. One dose of the acid stopped the sweating, which did not return for several weeks, although the man did not improve materially.

Case No. 670 was twenty-three years old, with chronic pulmonary tuberculosis. Sleep was impossible on ac-

[1] At Prof. W. H. Porter's clinic on general medicine, New York Post-Graduate Medical School and Hospital.

count of profuse sweats. One dose gave the relief desired.

Case No. 702 was a tailor, forty-eight years of age, with chronic pulmonary tuberculosis, complicated by repeated nasal hemorrhages, which were followed by periods of great sweating. Good nutrition and several doses of the acid gave relief.

Case No. 707, thirty-two years of age, had an acute attack of pulmonary tuberculosis, from which he seemed to partly recover. He complained a great deal of sweating and of dyspnea. Examination revealed a chronic pulmonary tuberculosis, involving the larger part of the right apex. Bacilli were found in the sputum. His sweats at times used to last all night. After this condition was ameliorated by the use of camphoric acid, he was greatly improved. Unlike the other cases, the sweats did not stop at once, but gradually became less and less, until they finally disappeared.

It will be noticed from the foregoing reports that only a very few doses were required to give prompt, and in many cases lasting, relief. After taking the camphoric acid all of the patients were able to sleep better, and on awakening, felt stronger and refreshed.

ENDOCARDITIS OF THE AURICLE AND RUPTURE OF THE CHORDÆ TENDINEÆ OF THE MITRAL VALVE.

BY CASPAR W. SHARPLES, M.D.,
OF SEATTLE, WASHINGTON.

THE subject of this note was a man about forty-five years of age, whose history is very brief and incomplete on account of his condition at the only time he was seen in life by the writer.

The essential points are these: He was a laborer, given somewhat to drink, subject to exposure, etc., an occupant of one of Seattle's lowest ten-cent lodging-houses. About eight years ago he had an attack of acute inflammatory rheumatism. He was sent to the King County Poor-farm, with a diagnosis of pneumonia.

The patient had a subnormal temperature; cold, livid extremities; a pulse rapid, very weak, irregular; and, at times, no pulsations could be detected in the radials; though, by stethoscopic examination, the heart was found to be beating. The vessels, both arteries and veins, at the base of the neck, pulsated freely. Respiration was rapid and shallow. Inspection showed a diffuse, undulating pulsation over the precordia, with the apex an inch outside of the nipple line and in the upper portion of the sixth interspace. No thrill could be found on palpation, and percussion showed a quadrate viscus. On making a stethoscopic examination, with the first sound a loud, rough murmur was heard, which could be traced into the axilla and back, and was well heard over the right lung. Just preceding the first sound and murmur was a second murmur, which, though presystolic in time, gave none of the usual characteristics of a presystolic murmur; and I am at a loss how to describe the sound. It was not soft, nor was it a squeak. It was very short. No symptoms of disease of other organs appeared.

In a few hours after I saw him he died; the section was made sixteen hours after death.

The cranium was not opened on account of darkness and lack of time. The large veins of the chest were engorged with dark, semi-clotted blood, and all four cavities of the heart were filled with the same material. The organ was large, quadrate, dilated, and the muscular tissue was soft and flabby; while there was general thickening of all the walls, except that of the right auricle. The thickening was especially noticeable in the left ventricle and auricle. No lesions were found on the right side.

Upon opening the left auricle a patch of old endocarditis was found, commencing at the free edge of the posterior leaflet of the mitral, and extending to near the top of the auricle, measuring over two inches in length. It was somewhat hour-glass in shape, being one and a half inches wide at the top, nearly two at the base, and only three-fourths of an inch in the middle. This patch presented smaller, roughened areas, raised not more than a sixteenth of an inch above the general endocardial surface. The largest was a fourth of an inch in diameter; then smaller, polypoid masses were found, closely constricted at the base. There were smaller areas of smooth endocardium among these masses, but these, too, were thickened. The vegetations extended to the anterior leaflet but sparingly, while the longest and highest mass was found at the left junction of the leaflets. One very narrow, thread-like vegetation, five-sixteenths of an inch long, was found on the valve. No disease was found on the ventricular surface of the valve.

The other pathologic conditions equally interesting are as follows: There was a rupture of the chordæ tendineæ, which were changed in appearance and character, being all that were attached, most anteriorly and nearest the center of the valve, with only one remaining on the left; thus leaving the valve to flap back and forth without its normal control. The longest chordal fragment on the valve was three-fourths of an inch long. It was softened, thickened, and beaded, smooth over most of its length, with one hanging vegetation.

Attached to another broken chorda was a mass half an inch long and one-eighth in diameter, fastened by a narrow, small, short pedicle. Otherwise it was free to flap about in the ventricle. The other chordæ presented no peculiarities, except that they were thick, soft, and very friable.

One of the transverse bands connecting two chordæ near their origin presented a large vegetation.

No ulcerations could be found anywhere in the heart.

The coronaries were stiff, with here and there a plate of calcareous deposit, and the vessels throughout the body were stiff. The heart-substance presented no peculiarities. The spleen had three recent hemorrhagic infarcts. Otherwise there was nothing of special note.

To me this was a unique specimen, and consequently I have described it more fully than I otherwise would have done. So far as my limited range of reading goes, I can find no parallel case.

The lesions of the chordæ are peculiar. In a fibroid heart are occasionally found thinned and lengthened chordæ, associated with a fibroid condition of the columnæ carneæ, which also may be thinned and lengthened. Our specimen presents no evidence of fibroid degeneration.

Again, associated with extensive chronic induration,

thickening, and distortion of the mitral may be found shrunken, shortened, and thickened chordæ, with one or two ruptured ones. In other mitral cases there may be a vegetative deposit around the attachment of the chordæ to the valve, or the chordæ may adhere to one another; and, in addition, they may be softened and friable, though rarely are they found ruptured.

In view of the infarcts, we might suspect an ulcerative endocarditis, but no ulceration could be found, nor any new vegetations. Their presence is easily explained by loosened fragments from the chordæ, which have, in turn, plugged the splenic arterioles.

Auricular endocarditis is a very rare condition, and such a one, too, would turn our attention to ulcerative endocarditis, as this affection has no regard for the place in which it plants its vegetations.

To interpret the presystolic sound is another question. The auricular endocarditis may explain all or a part of it, or it may have been caused by the sudden and rapid return of the valve. From the number of chordæ destroyed, and the post-mortem mobility of the leaflet, it seems that the systole of the heart would force the leaflet through the orifice into the auricle, it being carried back with the regurgitant blood, and then, in turn, the commencement of the auricular systole would force the valve back through the rushing blood-current, and thus produce this sound; or this fact and the auricular endocarditis combined would do it. However, from the position of the auricular part of the disease, unless it be that on the auricular surface of the mitral, I judge that this played no part in generating the presystolic murmur.

AN AGGRAVATED CASE OF CHOREA.

By GEORGE A. HIMMELSBACH, M.D.,
RESIDENT PHYSICIAN OF THE BUFFALO GENERAL HOSPITAL, BUFFALO, N. Y.

On Sunday, November 29th, a patient, Lena S., was brought to the hospital, who threw herself about in bed, all her extremities exhibiting constant violent and irregular movements. The facial muscles and tongue were also involved, causing distortion of the face and rendering her speech irregular and jerky, and at times even impossible. The case was promptly diagnosticated as chorea.

The following history was obtained from relatives: She was eighteen years of age, German, the youngest of a family of thirteen children. She came to this country one year ago, and her parents being in meager circumstances, the child was obliged to seek employment as a domestic. Menstruation began at the age of twelve years, and with the initial period came these irregular muscular twitchings, presumably choreic; they continued for a considerable time and finally passed away.

I could obtain no hint of hereditary neuropathic tendencies, save that a sister, the seventh child of the family, at the age of ten years, had symptoms that the parent described as similar to those in this girl, and which were very severe, lasting a short time and resulting fatally.

[Strümpell reports having seen three fatal cases of chorea in his private practice.]

During the three months prior to entering the hospital, the patient suffered from repeated attacks of articular rheumatism, affecting the joints of all extremities, and during the latter part of the three months she never left her bed. On the night of November 25th, four days before entrance, it was observed that her hands, arms, and legs were in a state of irregular contraction, and from this time the contraction gradually became more violent. At the time of admission she suffered from no rheumatic pains, but examination of the heart revealed most pronounced mitral and aortic systolic bruits.

She was first given calomel, 10 grains, also chloral hydras, 45 grains, in fifteen-grain doses, during the night; the following morning she was given large and frequent doses of sodium bromide and chloral, with little effect. Catheterization was necessary.

Antipyrin was now given in repeated ten-grain doses, in combination with the bromides and chloral, but all these proved of no avail. For four days the girl had taken no nourishment, except small quantities of milk given by the spoonful, carried to the posterior buccal cavity. Mastication was out of the question, and deglutition was possible only when she was fed in the manner indicated.

Nutrient enemata were now given, consisting of peptonized milk, peptonized egg, beef peptones, and whiskey. This method of feeding was continued for several days. During this time the girl's symptoms were growing worse and her movements more violent, so that restraint was necessary. Twice, when unobserved, she threw herself from her bed.

On December 4th, after the liberal use of bromides, chloral, and antipyrin, with no success, Dr. Stockton suggested hyoscine as recommended by Da Costa. I accordingly gave hypodermatically of the hydrobromate of hyoscine, $\frac{1}{100}$ grain, at 6.30 P.M., followed by $\frac{1}{50}$ grain at 10.30 P.M., and $\frac{1}{50}$ grain at 2.30 A.M. (December 5th). Each of these doses was followed by a short period of quiet. I next gave sulphonal in 20-grain doses, but with no more effect. It was now suspected there might be an hysterical element about the case; points of anesthesia were found, particularly the conjunctivæ, which, at times, were anesthetic. Mistura asafœtidæ, in large doses, was given, which seemed to dispel this condition.

It was now very evident that some other expedient must be undertaken. She had reached that point where food could not be tolerated, either by the mouth or by the rectum; in five days she had not had more than six hours' sleep. Her pulse was rapid, 164, and feeble; the temperature, 102.6°. She had moved and thrown herself about so violently that the shoulders, elbows, nates, heels, etc., were so badly chafed as to cause capillary oozing. It was finally decided to try a method recently advocated, consisting in strapping the body to a suitably arranged board, preventing even the slightest movement. Before trying this, however, it was suggested, as a last resort, to try morphine.

On December 5th, at 8 P.M., the sulphate, $\frac{1}{4}$ grain, was given hypodermatically. This was followed by the longest period of rest she had had. The effects of the drug passed off in a few hours and at 3.15 the following morning the same dose was again repeated. This was followed by the happiest results: sleep and

quiet ensued, lasting six or eight hours. From this time on, the chorea so abated as to call for no more sedatives.

In addition to the remedies directed toward quieting her, she was put upon Fowler's solution the day after entrance, commencing with gtt. v, t. i. d., and increasing one drop daily. This was continued until gtt. xvi were given t. i. d.; at this point the toxic effect of the drug was noticed, *e. g.*, puffiness of the eyes, gastric disturbance, markedly injected conjunctivæ, and cutaneous eruption. It was then discontinued for three days and again started on gtt. x doses.

As soon as she was restored to quiet, she began to take nourishment by the mouth, and improvement thenceforward was quite rapid. My attention was now called to the fact that the girl's right lower extremity was paralyzed. There was complete loss of extension; she could flex the limb to an angle of 90°, but extension was impossible. Sensation was only slightly impaired, the patellar reflex lost.

This I found to be not an uncommon sequel of chorea and described by writers as post-choreic paralysis (or paresis as in this case). Upon close questioning, I learned that monoplegia also followed her first attack of chorea, but passed away after several months. The treatment now followed was Fowler's solution, mist. asafœtidæ, strychnine, cold spinal douches, and faradism to the limb. In a short time the function of the limb was restored and the girl was discharged from the hospital apparently cured.

ACQUIRED CRURAL OVARIAN HERNIA.

BY JOHN S. MILLER, M.D.,
SURGEON TO ST. JOSEPH'S HOSPITAL, PHILADELPHIA.

THE following case is reported for the value it may possess as a contribution to statistics. Hernia of the ovary is a rare affection. It is generally congenital and bilateral, and is usually associated with some congenital malformation of the genital apparatus, such as the absence of the uterus or imperfect development of the vulva or vagina. Albert, in his *Lehrbuch der Chirurgie und Operationslehre*, quotes Englisch, of Vienna, who, in an exhaustive study of thirty-eight cases, found that in about three-fourths of the cases the hernia existed in the inguinal region, the others being obturator, ischiatic, umbilical, and crural ovarian hernia. The latter variety is quite infrequent. In a collection of seventy-eight cases, Puech found only sixteen in which the ovary passed through the crural canal, and it has never been found before the twentieth year; it is, therefore, never congenital. In the literature at my command I have found recorded but one case of acquired inguinal ovarian hernia as the result of a preëxisting intestinal hernia. Meadows (*Obstet. Trans.*, vol. iii) has recorded an interesting case, in which there was primarily an ordinary irreducible inguinal hernia. The tumor in this case gave rise to so much inconvenience that it was removed by a surgical operation.

Winckel, Tait, Englisch, Olshausen, and Albert agree that a large proportion of ovarian herniæ are congenital, particularly the inguinal variety, in which a vaginal process of the peritoneum forms, and causes the exit of the ovary in a manner analogous to the descent of the testicle. It is not improbable that the acquired variety may obtain in this region, owing to a lengthening or to elasticity of the infundibulo-pelvic ligament, or of the ovarian ligament. As the result of a strain or injury these relaxed ligaments may permit the ovary to be forced or to gravitate through a hernial canal that had been previously dilated by a reducible intestinal or omental hernia—the ovary taking the place of these structures, as was the condition in the case I am about to report.

The diagnosis of incarceration of the ovary is not generally made. (Only seven times in twenty: Englisch.)

Mrs. Y., forty years of age, robust, a German, the mother of six living children, has always enjoyed good health. Ten years ago, while straining or lifting, she felt "something give way," and soon noticed a *soft tumor* in her right groin. This she readily reduced by rubbing; but the tumor always returned when she worked hard. At the Woman's Medical College Hospital she was ordered a femoral truss, which, however, she only wore at long intervals, when the hernia troubled her most.

On October 15, 1890, after partaking of some improper food, she had a severe attack of vomiting, which was followed by pain in the right groin, and the discovery of a hard and painful tumor, which she was unable to reduce. She had not been wearing the truss just previously to this time. The pain soon subsided, and on the following day she went about her work as usual, and danced in the evening. On the following day I was called to see the patient for the first time, and found her uneasy and in pain. Upon examination I found a hard, sensitive tumor, about the size of a walnut, situated in the region of the femoral ring. It was slightly movable; the skin was not tender to the touch, nor did taxis, which failed to effect a reduction, cause much discomfort. I was at quite a loss to know with what I had to deal. The tumor felt like an inflamed lymphatic gland. The previous history, however, was suggestive of an omental hernia, but the entire absence of the characteristic symptoms of such a condition was puzzling. Having had the experience that absence of pain in strangulated hernia is a forerunner of a dangerous condition, I advised at least an exploratory operation; to which the patient readily assented.

On October 17th the parts were carefully shaved and cleansed. The patient was etherized. Having cautiously cut down through the various layers of tissue, I reached what was supposed by myself and other physicians present to be a thickened hernial sac. Upon opening it, to our great surprise it proved to be the broad ligament. I found neither intestine nor omentum, but a cystic ovary. When strong traction was made on the ovary, the right cornua of the uterus could be made to assume an oblique and anteverted position, and the wound being enlarged, the fundus of the uterus could be felt by the index finger. This procedure finally corroborated the diagnosis of hernia of the ovary.

The ovary was found in the hernial sac without the Fallopian tube or its fimbriated extremity. The strangulation at the crural ring was so severe that the ovary and its pedicle (broad ligament) were deeply congested, their vitality being undoubtedly greatly impaired. Not willing to run any risk by reducing the organ in this

condition, the pedicle was transfixed and tied as in ordinary oöphorectomy. Great care was exercised to prevent the entrance of blood into the abdominal cavity. The stump was thoroughly irrigated with boiled water, and dropped into the abdominal cavity. An assistant made a vaginal examination and found the uterus in its proper position.

The wound was united with two tiers of catgut sutures and left without drainage. The temperature did not rise above 99°, and the wound closed firmly under one dressing. At the conclusion of the operation it occurred to me that I had missed the opportunity of doing a unique operation for the radical cure of this patient's intestinal hernia. If the stump, which consisted entirely of the broad ligament, had been stitched to the ring and the deeper structures of the wound, it might have proved an excellent barrier to the descent of the gut. This procedure, however, would be open to severe criticism in case of a future pregnancy, and would, perhaps, be admissible only when both ovaries are removed, or if the menopause is close at hand. The patient remained in bed three weeks, when a suitable femoral truss was applied. She is now in excellent health, and is able to attend to her household duties.

CYST OF PERITONEUM RESULTING FROM IMPACTED GALL-STONES; AUTOPSY.[1]

BY J. H. McCASEY, M.D., C.M.,
OF CONCORDIA, KANSAS.

MISS R. S., fifty years old, a housemaid, presented a history of ague in childhood. Between the ages of seven and twelve years she had occasional attacks of jaundice. At sixteen she had an attack of typhoid fever lasting three weeks. As long as she can remember she has had pain in the right hypochondrium, so that "she could scarcely drag her right foot." Vomiting occurred with great readiness. She suffered with decided distention of the abdomen. Her life had been an active one, and she had been exposed to many hardships and privations.

Called to see her in June, 1890, I found the temperature 103°, the pulse 106, the abdomen tympanitic and extremely tender. I then diagnosticated peritonitis, expressing a suspicion of the existence of an abdominal tumor, but owing to the tenderness I could not make the examination conclusive. The patient was confined to bed for about three weeks, but recovered without further mishap.

On June 26, 1891, I was again called to the patient. The temperature was 102°, the pulse increased in frequency. She was suffering with severe dragging pain in the right hypochondrium and freely vomited bilious matter. The abdomen was distended, and there was perceptible bulging, with flatness on percussion, just below the liver. I told the patient that there was likely a cystic tumor, and that I would return in a few days to aspirate and remove the fluid.

On July 1st, with the assistance of Dr. Coffey, I withdrew about two quarts of dense, blackish fluid.

About July 17th, with the assistance of Dr. Sawhill, I withdrew about three-fourths of a bucketful of the same kind of fluid mixed with pus. About a week later, I again applied the aspirator, but failed to obtain any fluid. On August 11th, I succeeded in obtaining about three-fourths of a bucketful of pus. On August 16th, I introduced a trocar and canula, and permitted the canula to remain for five days, a continuous discharge of pus taking place. The woman died on August 27th.

At the autopsy, twelve hours after death, on opening the abdominal cavity in the mesial line, the peritoneum was found black and discolored. The gall-bladder was of medium size, and was filled with gall-stones—seven or eight in number, some as large as marbles. The small ones occupied the cystic duct. The liver was somewhat enlarged, but was otherwise quite healthy. Below the liver was a large cystic tumor, having a capacity of a gallon or more. Its inner walls were calcified. The sac was greatly thinned at several places. At the lower and posterior aspect a rupture had taken place.

With regard to cyst of the peritoneum, the *Reference Handbook* says that it is of so rare occurrence as not to claim mention in a work of that kind. Flint, Loomis, and all the text-books do not mention the subject at all, but refer to serous peritonitis, which most nearly resembles this case. But in this case we have a tumor-sac, and from the history of the case it would appear to have been in existence for twelve years. The inner wall of the sac had time to become calcified. I think all this establishes the diagnosis of cyst of the peritoneum and not chronic serous peritonitis, as might appear. The sac was badly decayed, and it was difficult to find its starting-point. But it seems probable to me that the gall-stones, or rather, hepatic colic, set up circumscribed peritonitis, which acted as a nucleus for the formation of the simple cyst of the peritoneum. Catarrh of the bile-duct or inflammation of the gall-bladder may often precede the formation of gall-stones and the mucus excreted serve as a nucleus for a gall-stone. An excess of the salts of lime or of bile-pigment or retention of bile may be exciting causes of biliary calculi.

A CASE OF ACRANIA.

BY G. W. PIRTLE, M.D.,
OF CARLISLE, INDIANA.

ON August 3d I was called to see Mrs. D., and found her in the first stage of labor. The bag of waters was protruding as a slender mass, like the fingers of a glove, an inch from the vulva. Upon very slight manipulation, it was ruptured during a pain that occurred just as I was attempting to make my first digital examination; a small quantity of amniotic fluid escaped. On completing my examination, I found a head engaging in the left oblique diameter, with the occiput anteriorly. By external manipulation I thought I could distinguish the presence of two bodies, but from the fact that the abdomen was greatly distended and tense I could not be positive. In a few minutes, an apparently healthy child was born, but it was very small, and died in about three hours.

Immediately after this child was born, there came a great gush of water, flooding everything completely, saturating the bed, and running through on the floor. After the first gush of fluid I made an examination and found an arm, with the hand slightly protruding from the vulva.

Upon passing my hand upward I was unable to find any round mass or anything that seemed to the touch like a head. But in the position where it seemed that the head should be (judging from the position of the presenting hand and arm) there was an irregular mass, different from anything that I had ever felt in obstetric practice. I was not a little perplexed, but decided to proceed at once on the orthodox plan and perform podalic version, which was accomplished without much difficulty, and the child was soon delivered. On examination a condition of acrania was found to exist. The absence of the brain was complete, the cord ending in a small bulbous extremity about five or six millimeters in diameter. The parietal and vertical portions of the frontal, and the posterior portion of the occipital bone were completely wanting. The squamous portion of the temporal bone seemed to be absent, and in its place was a round mass of bone. The anterior and middle fossæ of the skull were complete, but that portion of the cranium which is posterior to the foramen magnum was absent. Upon dissection I was unable to find positively the intra-cranial portions of any of the cranial nerves, although near the apex of the petrous portion of the temporal bone there was a mass of tissue that corresponded both in position and appearance to the Gasserian ganglion. The optic nerve terminated in a bulbous mass just at the internal opening of the optic foramen. The eyes were well developed and very prominent, giving the specimen the remarkable frog-like appearance so often spoken of in descriptions of acrania. The rest of the body was well developed, but small. When born, the heart was beating regularly, but its action soon became intermittent, though I was able to keep up a feeble pulsation by artificial respiration for several minutes. There was no attempt at respiration. In fact, the only movement perceptible was a slight tremor in the muscles of the lower limbs, which occurred when the bulbous extremity of the cord was touched.

This case is interesting for three reasons: First, it was a case of polyhydramnios; second, the presentation was abnormal; third, the fetus was a monstrosity.

Acrania is, perhaps, the most common of all important and striking monstrosities. The perplexity it gives the physician makes the subject of more importance than any impediment that it might cause in labor. One who has never attended a case in which the fetus has presented a condition of acrania cannot help feeling somewhat perplexed when, upon examination, the finger comes in contact with the floor of the skull of an acranial monster. In the case reported the presentation was one in which, had the fetus been perfect, version would have been required; but, from the fact that the head was incomplete, I am confident that it would have been delivered naturally; not feeling fully satisfied, however, I was unwilling to allow the child to become impacted in the passages.

The Corpuscle is the name of a twenty-four page journal published monthly by a board of editors constituted of undergraduates chosen from the classes of Rush Medical College, Chicago, by election. Number seven of volume one bears date of February 20, 1892, and does credit alike to editors, students, and faculty.

CASE OF INTUSSUSCEPTION IN AN INFANT.

By D. E. RUFF, M.D.,
of Junction City, Oregon.

In a medical experience of twenty-five years, I have never met a case of this kind in as young a patient as the one with the following history: On October 29, 1891, at 5 P.M., my child, a male, then seventeen days old, began crying severely. The mother gave some simple remedy for colic at the time, but this failed to give any permanent relief. At 6 P.M. a small dose of castor oil was given, as it had been frequently used with good results in the case of an older child. For a short time after taking the oil it stopped crying and began to strain or bear down, and moan, crying only occasionally and for a short time. At 10 P.M. it commenced to vomit and hiccough very severely; suspecting then something more than colic to be the trouble, I examined the bowels thoroughly and discovered a kidney shaped tumor on the right side, slightly tender and movable. Recognizing at once that I had a case of intussusception to deal with, I immediately gave an injection of lukewarm water, holding the child partly inverted. After five minutes' retention, the contents of the lower bowel were passed. I then held the child up by the shoulders and pumped air into the bowel, until the belly became quite tense, and used light friction over the bowels. I alternated the injections of water and air until midnight. I then gave chloroform, until the child was thoroughly relaxed, and used external manipulation over the tumor, pressing downward at each extremity and pulling the hands apart. In this manner I partially reduced the invagination to three inches, which at first was about five inches in extent. After emptying the lower bowel with the water first injected, there had been no movement of the bowels, and the later injections brought away only flecks of mucus.

At 2 A.M., the 30th, I gave a dose of morphine, so small that it would be difficult to tell how much. I had no hopes of his recovery. His features had now become pinched and drawn, and I gave the hypnotic to ease him of his sufferings, which were severe and very acute.

I still continued the alternate injections of water and air. At 9 A.M. he became more cadaveric in appearance, and he had every appearance of dying. As we had a good open fireplace, I had no trouble in keeping him warm, except the hands, which would get cold when exposed for only a few minutes. At 11 A.M. the bowels were moved, the action being of a very dark green color, with scattered flecks of undigested milk. His appearance now improved; he did not look so death-like. He was fully under influence of the opiate at this time. No change was noticed in his features or condition until 3 P.M., when he gave a severe and sudden start or jump, straightened out his legs for an instant, and then relapsed into a seemingly more natural sleep, the features clearing up, and the breathing becoming easy and soft. Examining the bowels now, I found the intussusception had become reduced.

In all the literature at my command, I cannot find a case like this, at as young an age, and I give a full history of the case. The child, at birth, weighed six pounds, and previous to this trouble the bowels had been too loose, moving eight or ten times in twenty-four

hours, with flakes of tough, stringy mucus and undigested milk, and occasionally the actions were of a dark-green color. At this date the child weighs thirteen pounds net, and is plump and hearty, and will laugh and crow when noticed; the bowels are in good condition, and the milk fully digested. He has never been fed artificially.

SEVERE "COMMON COLD" DUE TO REFLEXES FROM THE EYE.

BY GEORGE M. GOULD, M.D.,
OPHTHALMOLOGIST TO THE PHILADELPHIA HOSPITAL.

ILLUSTRATIONS of neurotic reflexes proceeding from nasal and naso-pharyngeal abnormalities are common, but instances of reflexes from the eyes to the nose, etc., are so rare that the following striking case should be known to others.

The vexing peculiarity about all such phenomena is that they may be taking place every day unrecognized by physician or patient. Had my patient and his family not been people of exceptional intelligence, the facts I am about to relate would not have been discovered.

Mr. W. H. P., forty-six years of age, a fine type of the clear-headed, well-educated, successful business man, consulted me May 10, 1890. His only complaint was of slight asthenopic trouble in near work. He had long known that he was near-sighted, but he did not care for better distant vision.

With paralyzed accommodation I found his error of refraction to be:

R. — sph. 2.25 D. ⊂ — cyl. 0.75 D. ax. 140°.
L. — sph. 4.00 D. ⊂ — cyl. 1.50 D. ax. 65°.

There was also exophoria of 6°.

It was with much difficulty that I prevailed upon him to wear for continuous use:

R. — sph. 0.75 D. ⊂ — cyl. 0.75 D. ax. 140°.
L. — sph. 2.00 D. ⊂ — cyl. 1.50 D. ax. 65°.

with prisms 2½° each eye base in.

He very soon came to like the glasses and wore them all the time. He would not get stronger glasses for distant use.

I heard nothing more from Mr. P. until the following spring, March 29, 1891, when his wife told me of her husband's excellent health, and that the past winter he had been free from the usual severe "cold," with which he had suffered every year the entire winter through for eighteen years. At this time none of us suspected the ocular origin of the "cold."

On April 3, 1891, I got my patient to order a pair of stronger lenses, correcting his myopia. In a week he "caught a wretched cold"—as he said, "in a sleeping-car." It was afterward learned that the day he caught the cold was the first day he had worn his stronger lenses.

On July 22d, he returned displeased with the stronger glasses. He had discovered that every time he wore them for an hour he at once had his old-time trouble of the nose and throat, consisting in great coryza, pharyngeal and laryngeal congestion, changed timbre of voice, etc. These symptoms always disappeared in a few hours upon a change to the weaker lenses. This fact he has since proved many times. If he goes to the theater or other public meeting, he frequently wears the stronger spectacles for an hour or two, for the satisfaction of more perfect distant vision. He invariably contracts the cold in so doing.

Not only this, but he has several times met with slight accidents to his weaker spectacles, so that becoming maladjusted, the axis of astigmatism was thereby improperly rotated. In such cases the cold reappears. Indeed, so routine has the phenomenon become that he now suspects maladjustment of the spectacle-frame whenever he begins feeling any nasal irritation. After a trip to the optician and a proper setting of the lenses, his cold disappears within about two hours.

Several lessons seem suggested by this case—to the general physician and rhinologist as regards the possible extra-nasal origin of nasal and pharyngeal trouble; to the oculist as to the remote effects of ocular strain, and also as to full correction of myopia; and to the patient and optician as to the maladjustment of astigmatic lenses.

MEDICAL PROGRESS.

The Urinary Ptomaines of Exophthalmic Goiter.—BOINET and SILBERT (*Revue de Médecine*, No. 1, 1892, p. 33) have succeeded in isolating from the urine of a patient with exophthalmic goiter, three ptomaïnes, inducing in animals symptoms analogous to those observed clinically. If extracted by an alkaline medium the ptomaïnes are designated α-ptomaïnes; if extracted by an acid medium, β-ptomaïnes. Each of these, according to its solubility, is named ethereal, amylic, or benzenic. The crude active principle obtained by evaporating the urine has a convulsant action. The amylic α-ptomaïne causes slowing of the heart, enfeeblement of the systole, arhythmia, prolongation of the diastole, and arrest of the heart in diastole. The benzenic α-ptomaïne gives rise to passing diminution in the energy of the systole, then to transitory increase in the systolic amplitude; subsequently there follows an enfeeblement of the systole and an augmentation of the diastole. The ethereal α-ptomaïne produces a slowing of the heart's beat, with a diminution in the energy of the systole, followed by an acceleration of the heart's beat, with an increase in the systolic amplitude, and finally cardiac weakness; the heart is arrested in systole. The amylic β-ptomaïne gives rise to passing augmentation of the energy of the systole, followed by enfeeblement of the heart's beat and arhythmia; the heart is arrested in diastole, from paralysis of the muscular fiber. The amylic β-ptomaïne causes slight depression of temperature, followed by elevation. The ethereal β-ptomaïne increases the amplitude of the systole and causes muscular resolution.

Two Cases of Abscess in the Region of the Medulla Oblongata.—EISENLOHR (*Deutsche med. Wochenschrift*, No. 6, 1892, p. 111) has reported two interesting cases of abscess in the region of the medulla oblongata. The one occurred in a man, forty-three years old, with bronchiectasis and empyema. One arm and one leg first became paralytic and anesthetic, and then the extremities of the opposite side. The reactions of the left pupil were deranged. The patient died in marked dyspnea. At the autopsy, an abscess, as large as a pea, was found in the medulla oblongata, beneath the floor of the fourth

ventricle, extending by a prolongation into the cord and involving the posterior roots and gray matter as far as the second cervical root. The second case occurred in a man, twenty-five years old, in the course of an attack of cerebro-spinal meningitis. The reactions of the pupil were deranged; there were general cutaneous hyperalgesia and unilateral facial paresis; consciousness was impaired; severe epileptiform convulsions set in; and death ensued. At the autopsy, in addition to the lesions of cerebro-spinal meningitis, a minute abscess was found at the level of the corpora quadrigemina, close to the aqueduct.

A Bullet in the Brain for Twenty-nine Years.—Conniff (*Vis Medicatrix*, i, 5, 1892, p. 279) has reported the case of a man, sixty-three years of age, whom he was called to treat in an attack of enteritis. There was, besides, a history of pain in the head and an inability to lie on the right side. Inquiry elicited the fact that twenty-nine years previously the man had received a gunshot wound at the left angle of the mouth, the bullet, it was supposed, entering the brain. The patient maintained that upon rotating his head he could feel the missile just back of the left ear. He had suffered almost constant headache, at times most intense and attended with vertigo. Hearing was lost on the right side. Vision was impaired on the left. The patient died, and at the autopsy, in addition to the lesions of a plastic enteritis, a bullet was found imbedded in the occipital lobe of the left cerebral hemisphere, behind the posterior cornu of the lateral ventricle. The bullet had entered near the left angle of the mouth, passing beneath the malar bone and entering the cranium through the left orbital cavity close to the optic nerve; thence it had passed toward the left lateral sinus.

An Immunity-conferring Principle in the Blood of Animals Treated with Tuberculin.—Having observed some degree of immunity in tuberculous guinea-pigs treated with tuberculin, Tizzoni and Centanni (*Centralbl. f. Bakteriol. u. Parasitenk.*, xi, 3 u. 4, p. 82) preceded injections of suspensions of tubercle-bacilli into the jugular vein by the introduction of the serum of the blood of such animals into the peritoneal cavity. Of ten animals thus treated, five died. All presented local lesions at the site of inoculation. In the fatal cases death was deferred and the visceral lesions were less extensive than usual. The view is expressed that tuberculin is, or the soluble products of the tubercle-bacillus are, capable of conferring a certain degree of immunity dependent upon the presence of an active agent in the blood, and that the good effects of tuberculin do not result from a direct action, but are dependent upon the generation in the body of some protective principle, which it is hoped future investigations will succeed in isolating.

Enteric Fever in an Infant Nine Months Old.—Fuller (*Lancet*, No. 3558, p. 1038) has recorded the fatal case of an infant, nine months old, that presented manifestations of irritability and dulness, with diarrhea, tympanites, and elevation of temperature. At the autopsy, though the spleen was not enlarged, Peyer's patches were found swollen above the surface of the mucous membrane, some of the lower ones beginning to ulcerate. The adjacent intestine was injected. The mesenteric glands were enlarged and the solitary glands of the cecum were abnormally prominent. In the same house in which the infant lived, an older child of eighteen months, as well as a woman, presented symptoms similar to those of the infant.

Filariosis.—Moty (*Revue de Chirurgie.*, No. 1, 1892, p. 1) reports six cases of filariosis observed at Val-de-Grâce. The most common manifestation was dilatation of the lymphatics of the groin and spermatic cord, dependent upon the irritation of the filariæ or their embryo. The diagnosis may be made upon the clinical manifestations, but is to be confirmed by the detection of the embryos in the blood. Internal treatment is useless. Palliative external treatment is not to be commended. If the manifestations are decided, surgical intervention, with the removal of the parts most involved, is indicated. It may thus be possible to remove the adult filaria.

A Hitherto Undescribed Anomaly in the Mechanism of Labors in Face Presentation.—Hirst (*University Medical Magazine*, iv, 5, 1892, p. 341) has reported a case of labor terminating fatally, in which the face presented, the mechanism being complicated by a hitherto undescribed anomaly. The abdomen of the child was turned slightly toward the right, the back to the left, anteriorly. The face was transverse, the chin directed slightly posteriorly. The occiput and the right shoulder were in close apposition. Descent of the head was impossible, while extension was prevented by the position of the right shoulder.

Atrophy of the Maxillary Bones in Posterior Spinal Sclerosis.—According to Rosin (*Deutsche Zeitschr. f. Nervenheilk.*, 1891) it is not rare in the course of posterior spinal sclerosis, not only for the teeth to fall out, but also for atrophy of the alveolar margin to take place, either by absorption or by sequestration. The inferior maxilla is less frequently affected than the superior maxilla. The mucous membrane in the atrophic areas is anesthetic. These associated manifestations may occur early or late in the course of the disease.—*Journal de Médecine de Bordeaux*, No. 5, 1892, p. 63.

Toxic Effects of Impure Chloroform.—As a result of experiments on animals conducted in the Pharmacologic Laboratory of the University of Berlin, Dubois-Reymond (*British Medical Journal*, No. 1622, p. 209) has found that the toxic effects of chloroform are greatly increased by the presence of impurities. By the method of Pictet, of crystallizing chloroform by intense cold, it was possible to separate the pure drug from impurities. The latter occasioned greater frequency of pulse, greater depression of blood-pressure, and cessation of respiration more quickly than did the former.

The Temperature in Old Age.—As a result of continuous observations made under uniform conditions of health, in the cases of three persons, aged eighty-two, eighty-three, and eighty-nine years respectively, Kelynack (*Medical Chronicle*, xv, 5, p. 289) has found that the temperature, as registered in both rectum and axilla, is

distinctly below that of healthy children and adults. The rectal temperature was from one-fifth to one degree higher than the axillary temperature.

THERAPEUTIC NOTES.

For Fetid Breath.—

℞.—Thymol . . . . . ʒj.
Borax . . . . . ʒij.
Alcohol . . . . . f ʒiij.
Distilled water . . . f ℥ijss.—M.

S.—Use several times a day as a gargle.

Or,

℞—Salicylic acid, Saccharin, Sodium bicarbonate } āā gr. xvj.
Alcohol . . . . . f ℥j.—M.

S.—f ʒ in water, as a gargle, several times daily.

Journal de Méd. de Paris.

Palatable Castor Oil.—As the result of a series of experiments, STAADKE (*Deutsche medicin. Wochenschr.*, 1892, No. 4, p. 87) believes that he has succeeded in removing the nauseous taste of castor oil. The best castor oil is repeatedly treated with hot water, then sweetened with sufficient saccharin to possess a syrupy taste. Minute quantities of the aldehyde of cinnamon oil and of vanilla flavoring suffice to completely cover whatever disagreeableness of taste remains. Oil so prepared has been found to be as efficacious and as permanent as the ordinary oil.

For Coryza.—

℞.—Cocaine hydrochlorate . . gr. ix.
Menthol . . . . . gr. xv.
Coffee, parched and finely pulverized . . . . . gr. xxx.
Boric acid . . . . . ʒij.—M.

S.—Take five or six good pinches, as a snuff, a half-dozen times daily.

COUPARD, *Monde Therapeutique.*

Treatment of Hiccough by Compression of the Phrenic Nerve.—At a meeting of the Académie des Sciences, LELOIR (*Journal de Médecine de Bordeaux*, 1892, No. 5, p. 59) reported the successful treatment of a considerable number of cases of otherwise incoercible hiccough, by means of digital compression of the phrenic nerve, for from a few seconds to a few minutes, between the two clavicular attachments of the sterno-cleido-mastoid muscle.

For Chronic Rheumatism.—

℞.—Sodii iodidi . . . . ʒij.
Sodii bicarbonatis . . ʒiv.
Potassii bicarbonatis . . ℥j.
Liquor. potassii arsenitis . f ʒjss.
Decoct. sarsaparillæ comp. ad f ℥xx.—M.

S.—A tablespoonful in considerable water three times a day after meals. WHITLA.

For Acne.—The following formula is recommended for internal administration in cases of acne associated with anemia:

℞.—Ferri sulphat. . . . gr. xxiv.
Acid. sulphuric. dilut. . . f ʒj.
Magnesii sulph. . . . ʒiv.
Sodii sulph. . . . . ʒiv.
Aquæ menth. pip. . ad f ℥xij.—M.

S.—Two tablespoonfuls before meals. WHITLA.

For Psoriasis of the Scalp.—The following ointment may be employed in psoriasis of the scalp if the disease be limited and there be no irritation.

℞.—Salicylic acid, Pyrogallic acid } . . āā gr. xxiv
Ichthyol . . . . . gr. xlviij.
Soft potash soap, Vaselin } . . āā ℥j.—M.

S.—Apply cautiously on alternate days with gentle friction.

BESNIER, *Revue Gén. de Clin. et de Thérap.*, 6, p. 89.

For Moist and Painful Leg Ulcers.—The following has been successfully employed as a topical application in the treatment of moist and painful ulcers of the leg:

℞.—Acid. salicylic. . . . . ʒij.
Acid. boric. . . . . gr. lxxij.
Zinci oxidi . . . . . gr. xlviij.
Amyli, Pulv. talc. } . . . āā ℥j.—M.

WEISMÜLLER.

A Deodorant.—When, in case of carcinoma of the uterus, a deodorant is required, the following combination will prove useful:

℞.—Acid. salicylic. . . . gr. viij.
Sodii salicylat. . . . ʒiij.
Tinct. eucalypti . . . f ʒvj.
Aquæ destillat. . . . f ℥vj.—M.

S.—Three tablespoonfuls are added to a pint or two pints of water, and used as a douche every three or four hours. WHITLA.

Gall-stones.—In an interesting paper on gall-stones, GOODHART (*British Medical Journal*, No. 1622, p. 219) expresses the view that in many cases the formation of such calculi appears to be related to some mental strain or to a neurotic condition. He has seen beneficial results follow the administration of olive oil. For the itching of the skin that attends the jaundice he recommends pilocarpine, by the mouth or hypodermatically.

Treatment of Goiter.—AUERBACH (*Deutsche medicin. Wochenschr.*, 1892, No. 3, p. 60) recommends interstitial injections of osmic acid in the treatment of goiter. One-twelfth of a grain, in solution, is injected daily into the tumor, followed by a massage for fifteen minutes, while potassium iodide is given internally.

A Deodorant for Iodoform.—The ethereal oil of coriander is recommended as a deodorant for iodoform. It is directed that eight drops of the oil be thoroughly incorporated with a dram of iodoform.

RECENT PROGRESS IN THE STUDY OF THE BLOOD.

ADVANCES in the medical sciences are so rapid and publications so numerous that occasional "stock-taking" becomes a necessity, lest the facts acquired be engulfed and hidden in the very mass of contributions that gave them forth. A review of recent progress in the knowledge of the diseases of the blood is at once a profitable and pleasant work, for in few branches of medicine will we find advances so far-reaching in the results already attained, so promising for the future.

Someone has said that we owe as much to the maker of instruments of precision as to ourselves for the advances in modern science, and assuredly there is more than a grain of truth in this. Without the hemocytometer, the hemoglobinometer, and the microscope we should still remain in ignorance of many well-established principles, valuable in diagnosis and still more so in treatment. Without these aids we might find consolation in the words of a prominent therapeutist, who says: "How interesting to be able to count the corpuscles and measure the hemoglobin, but I see by the skin that this is anemia, and my studies teach me that iron cures anemia." Doubtless it is true that we may diagnosticate anemia by the appearance of the skin, but aside from any thought of the fact, so well stated by SANSOM, that "no disease is well treated that is misunderstood," practical experience and scientific investigation have demonstrated that there are cases of anemia and anemia, often distinguishable, not by the hue of skin or the clinical history, but by the careful study of the blood, and by this alone.

It has been sufficiently established that there are three classes of anemia readily distinguishable by the condition of the blood: first, simple anemia, in which the hemoglobin and the number of red corpuscles are correspondingly diminished; second, chlorosis, in which the hemoglobin is lessened far out of proportion to the diminution in the number of the red corpuscles; and, third, pernicious anemia, with its proportionately overwhelming decrease of red corpuscles and the relatively increased richness in hemoglobin of the individual corpuscle. These may be taken as types, to one or the other of which all the various forms of secondary anemias may be referred; and if future observation fails to confirm our present views (LAACHE) that iron is of especial value when the chlorotic character is assumed, and arsenic when the blood is especially poor in the number of its corpuscles, it has been proved beyond dispute that the examination of the blood for the determination of the type to which a case of anemia belongs is of the utmost service in establishing the diagnosis, and therefore the prognosis and treatment.

It is to the point to cite cases, such as those reported by MOUISSET, of Lyons (THE MEDICAL NEWS, February 13, 1892), cases of carcinoma of the stomach, in which the constantly increasing cachexia assumes the aspect of pernicious anemia, but in which the blood is of decidedly chlorotic character. We recall the case of an old man with most profound anemia, with increasing weakness, and pallor and slight fever at times, but without palpable tumor of the epigastric region, and without vomiting except from indiscretion in diet—in short, a picture of pernicious anemia, and yet, by discovering a chlorotic condition of the blood, or at least a condition not approaching pernicious anemia, we were enabled to diagnosticate malignant disease, and autopsy confirmed the diagnosis. So, too, there are occasional cases of tuberculosis, of malaria, of chlorosis, and other diseases—not a few of them curable—in which the outward manifestations mimic

this grave blood-disease, and which are distinguishable from it only by examination of the blood itself. What, then, are we to say of him who sets aside such valuable aids for diagnosis, and tells us it is possible to see by the pallor that there is anemia?

Another great group of cases to which attention must be directed, and the study of which has received renewed impetus of late, are those in which the leukocyte plays an important rôle. Since 1846, when VIRCHOW first recognized leukemia as a blood-disease and set aside the faulty notions of the older pathologists about "suppuration of the blood" and "hemitis," observations have been steadily accumulating, but none compares in importance with those of EHRLICH on the nature of the white corpuscles in health and disease. In pointing out that our old conception of leukocytes as simple masses of protoplasm, with ameboid motions, was not comprehensive enough, and that there are various kinds of leukocytes widely different in nature and origin, and in offering a ready means of distinguishing these, EHRLICH has contributed knowledge that has already yielded rich results and that will accomplish much more. It would be far from the present purpose to review the work of EHRLICH, even briefly, but we may state that by peculiar methods of staining he has succeeded in establishing five varieties of leukocytes in normal blood and in determining their relative proportions, and that he has found in the blood of leukemia a greatly increased number of one of these forms, and besides, a form such as is never found in conditions of health (myelocytes).

Such being the case, it will be readily seen that, aside from the high scientific value of the observations themselves, that he has placed in our hands the means of distinguishing the various forms of leukocytosis from the cases of true leukemia, since in the former the corpuscles present to a great degree the normal characteristics and relations. We would direct attention in particular to the varied forms of disease in children, so well detailed by LUZET,[1] in which, besides enlargement of the spleen, there is also more or less marked leukocytosis. Among these may be named congenital syphilis, rickets, and that peculiar form of disease described by JAKSCH as infantile pseudo-leukemia — all resembling true leukemia, but distinguishable, as LUZET and also BAGINSKI[2] have shown, by the color-tests of EHRLICH. The resemblance of these diseases, and sometimes other diseases of childhood as well, to leukemia, while usually not so close as to require special means of diagnosis, at times becomes so marked that the character of the leukocytes, as determined by EHRLICH's methods, alone serves to make the diagnosis. So, too, in cases of chronic malaria in adults, the enlarged spleen, the progressive anemia and weakness, together with marked leukocytosis, present a complex of symptoms scarcely to be distinguished from leukemia, except by the character of the leukocytes. The practical utility of these methods could receive no better illustration than the case of TOULMIN and THAYER,[1] one of leukemia, in which, under treatment, the spleen diminished in size, the general symptoms abated, and the excess of leukocytes disappeared. In such a case it would be impossible to diagnosticate leukemia, except that, as was actually found, there still remained myelocytes and the proportions of the different forms characteristic of the disease. Subsequent relapse, with reappearance of the symptoms, confirmed the diagnosis. The value of these investigations cannot at the present time be rightly estimated, for we have yet much to learn of the extent to which they are applicable, but the few examples cited are sufficient to indicate the immense importance of continued study in this branch of pathology.

Still another line of research demands notice—the study of microörganisms and foreign elements in the blood. It is noticeable how little bacteriology has accomplished in this direction, for though many microörganisms have been found in the blood, there are few the detection of which serves any practical purposes; of these we may mention the malarial organism, the spirocheta of relapsing fever, and the bacillus of anthrax. Whatever the future may determine as to the nature of the malarial organism, or its exact relation to the disease as a cause, there can no longer be any dispute as to its value for diagnosis. We may call attention to the recent paper of DOCK[2] in connection with this subject. Examination of the blood for anthrax-bacilli may be of great interest in cases of intestinal anthrax consequent upon meat-infection, and may be the means of establishing the diagnosis.

In thus reviewing some of the practical points in the recent advances in the study of the blood, we hope that it is clear that a more general adoption of

[1] Johns Hopkins Hospital Bulletin, May–June, 1891.
[2] THE MEDICAL NEWS, May 30, 1891.

these means of investigating disease has become a necessity. We are well aware of the obstacles in the way of the introduction of such methods in private practice, but even in our hospitals they have been neglected, and here the scientific value of such work alone should have been sufficient to secure its introduction.

We might enlarge greatly, and extend our remarks to the researches into the nature and cause of the blood-diseases, chlorosis and pernicious anemia in particular, or to the studies of the physiology of the blood-making organs, stimulated by the new methods of investigation furnished by Ehrlich, or the promising questions of antagonism between the fluids of the blood and microörganisms, but the purpose here has been to direct attention only to the practical side of these questions, and to urge a more general practice of methods of study that must prove of the greatest value.

CONCEALED GOUT.

Our last issue contained an interesting and valuable paper on "Obscure Forms of Gout," that had been read before the College of Physicians by Dr. Dulles. In the discussion elicited by this paper, it was truthfully said that the author had not done full justice to the knowledge and diagnostic acumen of his colleagues. Certainly, no such widespread ignorance of the subject prevails in Philadelphia as one might infer from the language used by Dr. Dulles. Nor do we believe that such ignorance prevails anywhere in the United States where the Alumni of Jefferson Medical College have gone. In each year of the more than twenty years that Professor DaCosta has taught at Jefferson, he has called frequent attention to the subject in his didactic and clinical lectures; and it would be simply impossible for any considerable proportion of his pupils to be uninformed concerning it, even if they had never looked into a book or read a journal. The occurrence of "half-gout," "American gout," or "lithemia," has thus become a matter of common knowledge, and has yearly been handed down to new classes by teachers that he has taught. Doubtless, other colleges and other chairs might be similarly cited, but we are simply offering personal testimony, not hearsay. The small number of papers by Americans to which Dr. Dulles refers, may be accounted for on a more flattering hypothesis than that of ignorance. The earlier authors treated the subject so thoroughly, and made it so familiar, that they left little for competent successors to add, and made unfamiliarity with the facts among the profession at large impossible.

Dr. Dulles's paper, apart from the point criticised at the meeting and in these lines, is a good and timely one, and will no doubt assist In the better diffusion of the knowledge of an important subject.

PROTEST AT ONCE.

The News has no interest in politics, and for that reason feels free to protest when politics injures medicine. Our indignation is stirred by the fact that under the provisions of the Army Appropriation Bill, reported by the Military Committee to the House of Representatives, the usual annual appropriation for the Library of the Surgeon-General's office, U. S. Army, is cut down one-half—that is, it is reduced from ten thousand to five thousand dollars. If this is not changed, either in the House or in the Senate, the result must be that the formation of a complete medical library at Washington, which has been going on so successfully for the last ten years, must be stopped—that all the new medical books and journals can no longer be purchased—to say nothing of the prevention of purchases of valuable works still required to make the collection what it should be—an absolutely complete reference medical library for the use of the United States.

When a member of Congress dies, "a junketing tour" with Pullman cars, etc., costing us thousands of dollars, is made to appear as a part of the funeral honors, and expenses. Every year every representative votes himself, his family, his friends, his clerks, and his pages high-priced pocket-books, ink-stands, knives, etc.; quinine, drugs, and all manner of "druggists' sundries"; soaps, puff-balls, cologne, silver hair-brushes, and every sort of toilet article imaginable—an infinitude of expensive trash, the total amounting to nobody knows how many thousands of dollars.

Then he would cripple medical science, education, and progress by reducing the already too small appropriation for the National Medical Library!

Every reader of The News, every physician of the United States, should immediately write his representative at Washington protesting most earnestly against such an outrage.

SELECTION.

A PLEA FOR HOME INDUSTRY FROM A MEDICAL POINT OF VIEW.[1]

A FEW days ago I had a strange dream, and since then I do not find any peace of mind. The question of protection, free trade, home industry, etc., haunt me by day and night. After you have heard the story of my nightmare you will understand why I presume to talk politics in a medical society.

I dreamed that I was sitting in the gallery of the House of Representatives. Hon. Nulite, a Representative of the recently annexed State of ——, introduced the following bill:

WHEREAS, Graduates from our regular and lawfully incorporated medical schools, citizens of the United States of America, have fallen of late into the bad habit of leaving their motherland, travelling into strange countries, and thus depriving our country for a certain period of time of their services as useful citizens in their respective avocations; and,

WHEREAS, The number of said birds of passage has increased in a geometric ratio, and from information gathered through our European consulates it appears that the number of said unpatriotic sons had, in 1891, reached the alarming number of 2000 souls, and allowing the expenses of each of them to be $1000 per annum, a simple multiplication will reveal to us that our National wealth is decreased by the colossal sum of two million dollars yearly; and, further,

WHEREAS, From personal interviews with many of said M.D.'s, I have learned that the motive for this, their strange behavior, is none other than the supposed imperfect and unsatisfactory method of teaching now prevalent in the medical schools of our country, and that they look upon themselves as upon so much *raw material* exported annually; therefore, in order to rectify this crying evil, to prevent our citizens from running away, and our National wealth from being exhausted, and to protect our home medical industry,

BE IT RESOLVED, Such M.D.'s should be entered upon the tariff list under the appropriate article, and be obliged to pay duty into the Custom-house of the United States in the sum of $1000 for each and every year of absence, or any part thereof. This fund shall be known as "Duty on those wanting to know too much," and said fund is to be divided, share and share alike, among those loyal subjects and faithful citizens who, having once got their medical degree, do not bother their heads about perfection, who are patriotic enough to stay where they are, prescribing ointments and powders, pills and capsules—in short, performing their duty to God and their fellowmen to the best of their knowledge.

Having finished reading the above remarkable document the Representative looked triumphantly upon his fellow law-makers.

"Protection"—continued the Representative—but this word fell like a blow upon my head, and I awoke. For quite a while I was stunned. What, thought I, I will have to pay $1000 when I go back? Heavens!

Whenever I think of that dream and my imaginary Representative, I cannot help finding in his words some grains of truth. The more I ponder over the "Whereases," the less ridiculous does his patriotism appear to my mind. The absurdity lies in the mode of solving the question—in his protective aspirations. Otherwise he is quite a sane man.

I have found that the American medical students in Europe can be divided into three groups: The first constitutes an insignificant minority. It is made up of those that go to Europe for the sake of the name alone. They roam all over Europe, they visit all the universities and café-chantants, they know all the names of the celebrities and of the bacilli, and they pronounce "prosit" in a pure German-kneipe way.

The second group is composed of elderly medical men—physicians who have been in practice several years. They came here either to refresh their memory, or to take a course in some special branch. Among them are a few who aspire to a professorship in some college. They are serious men, and know what they want.

The third group, the bulk of the American students, is composed of those who have just graduated. They have not had any experience, they do not aspire to professorships, they do not want anything especial—only the earth—of medical knowledge!

But what is there amiss at home that we are obliged to come to Europe? What is wanting there? Teachers? Not at all. Da Costa is as great as Gerhard, Price operates as well as Gusserow, Keen is as keen and daring as Bergmann, Pepper knows diseases of children as well as Henoch, and Weir Mitchell is not below Mendel. These are famous men of only one city—Philadelphia. Their number would reach hundreds if we would enumerate the great men of New York, Chicago, Cincinnati, Baltimore, etc. We may not have produced a Virchow, Koch, DuBois Reymond, etc. But Virchow does not give birth every nine months to a cellular theory, Koch is not pregnant all the time with new bacilli, and DuBois Reymond does not make a new discovery every day. All that they have discovered they have not patented—he who wants to know may learn it gratis. All that which we hear in the Berlin clinics we might as well have heard staying at home, and in a language more musical and comprehensible.

Wherein, then, doth the secret lie? I know that you divine what I am going to say: We have plenty of didactic lectures and very little of practical clinical work.

We boast of being an eminently practical people. "Let us see!" "Let us try!" "Prove it!"—are always on our lips. Medicine alone is our weak point; there we are all theory.

There are as many sick people in New York as in Berlin. There are in New York as many and as good hospitals as in Berlin. Why not deliver the same lectures at the bedside of the sick? Our children in the kindergartens are taught by the object method. Show us the sick man you talk about, and we will stay at home, otherwise we will go to Europe to see him. Build a pathological institute, and then talk of yellow liver atrophy; otherwise we will have to go to Europe for a

[1] Selections from a paper read by Dr. Charles D. Spivak before the American Medical Society of Berlin, in the auditorium of the Königliche Zahnärtztliche Akademie, February 4, 1892.

specimen. Erect a bacteriological institute, and we may believe that there are such vibrionic devils in existence. In Europe we see and cultivate them.

If anybody thinks that we need a Virchow to instruct us in pathology, he is mistaken. It is not the great men who instruct us here—you know this well—it is their assistants. And I can assure you that there are men in my own city who know as much pathology and bacteriology as the assistants of Virchow and Koch. They have no opportunity to apply their knowledge.

True, the recent inauguration of graded courses in all the respectable medical colleges, the splendid pathological institute in New York, the Johns Hopkins University—the future medical Mecca of the United States—show the dawn of a new era. But the progress is very slow. Conservatism is a noxious weed, difficult to root out. Look at our professors. They make flying trips to Europe almost every year. They see everything and everybody. They take back with them catgut, a new pessary, a pair of delivery forceps, a good-for-nothing obstetrical table; they tell us about the celebrities they have met, and they continue year in and year out their routine ways of instruction!

Before I close my paper let me appeal to you, gentlemen, that when you return home safely, well laden with practical knowledge, you should raise your voice in behalf of a new era of teaching. Some of you will rise in the profession, others will hold exalted positions, social or governmental, and a few will occupy chairs in colleges. For the sake of our profession do not forget the real motives of your visit to Europe. Do not compel your own pupils to seek for *practical* knowledge in some foreign land. Let the student be permeated with the atmosphere of the hospital and the laboratory. The ideal student of the future, in my opinion, will have to serve his apprenticeship as a nurse. The preceptorship of days gone by was better than many of the modern American medical schools.

Dr. Edward P. Davis, the editor of the *American Journal of the Medical Sciences*, writes to me:

"I quite agree with you in the contrast of methods of instruction in Europe and America; I think that the differences in government have much to do with it, as such institutes as you describe are subsidized in Europe by the Government, and can be supported in a way which is impossible in America."

Notwithstanding my personal dislike to any paternal Government, and my firm belief in the wisdom of keeping science apart from politics, yet if we cannot help ourselves in any other way—why, in the name of common sense, let us get money from the Government. Thank Heaven! there is always a little something saved up in the coffers of Uncle Sam.

Let me hope that you will do all in your power to further and develop the medical sciences in general, and aid in the speedy inauguration of wiser methods of teaching in our American medical schools in particular, and then the day will be nigh when we can exclaim:

"Three cheers for Home Industry from a medical point of view!"

Cocaine and Sulphonal.—It is announced that by an Imperial decree the employment of cocaine and sulphonal has been interdicted throughout the Turkish Empire.

CORRESPONDENCE.

"INFECTION" AND "CONTAGION."

To the Editor of THE MEDICAL NEWS,

SIR: I was much pleased when I took up the last number of THE MEDICAL NEWS, to see the title "'Infection' or 'Contagion?'—a Question of Definition," at the head of the editorial page, for certainly these terms are used very loosely, and whatever will give them a clearer definition will be of much practical value in classifying all discussion in which they are used. I only regret that I cannot wholly agree with you in your conclusions and recommendations. It is most certainly true, as you suggest, that it would be very desirable to have one generic word (for which you recommend zymotic), and let others be included within this, which shall apply to those diseases the *materies morbi* of which respectively are and are not carried by the atmosphere. And there is certainly no etymological objection to the use of the words that you suggest. But good usage is the arbiter of definitions, and if good and general usage sanctions a certain definition, it seems to me that it is unwise and conducive to the continuance of misunderstanding to urge any other definition, even though it be the more desirable. As regards "infection" and "contagion," these words as used by those who have occasion to employ them most frequently and with the most exactness, have, I have thought, acquired a very definite and much broader meaning than you would give them. Infection is very generally used in the sense given by Foster in his first definition, viz., "The act or process by which disease is set up in an organism by the implantation of morbific germs from without. . . . ." Thus the American Public Health Association has a standing committee on Preventive Inoculation in the Infectious Diseases, meaning thereby all diseases which were formerly included in the term zymotic. If I mistake not, this broad meaning of infectious is the one in which it is used by Sternberg, Welch, Prudden, Ernst, Gerster, Vaughan and Novy, and many other American sanitarians, bacteriologists, and chemists. Indeed *infectious* is used to include even more than the "germ" diseases, for it is applied by Leuckart to infection by trichinæ and other macroscopic parasites, and by Vaughan and Novy to diseases produced by ptomaïnes. Among English writers and in English laws infectious disease is commensurate with germ or zymotic disease, as may be instanced in writings of Sanderson, Klein, Simon, Newsholme, and Wynter Blyth. The like use is universal on the Continent, and the *Infectionskrankheiten* of the German Sanitary Bureau is even broader than "germ diseases," and is so used by Koch, Fraenkel, Hueppe, and indeed all German authors that I recall. Among the French, *maladies infectieuses* has about the same general meaning as *Infectionskrankheiten* among the Germans, and is employed in such a sense by Pasteur, Metschnikoff, Gamaleïa, Roux and Yersin.

Contagion is generally employed, by those whose usage I think should be authoritative, very nearly in accord with Foster's first definition, viz., "The communication of disease from one individual to another by means of direct or mediate contact. . . . This is

substantially Prudden's definition. So, too, when we ask, as so many have in the last score of years, "Is consumption contagious?" the desire is to know, not whether it is transmitted by contact, but whether its cause can be carried by the air or in *any* way.

The best and most general usage to-day defines *infection* as the poisoning of the body by living organisms or their products, and *contagion* as the transmission in any manner of the *materies morbi* from one living body to another.

This use is so general, that no matter how strongly it may meet with our disapproval, it seems to me the greatest aid we can give to clear writing is to conform to it. Respectfully yours,

CHARLES V. CHAPIN.

PROVIDENCE, R. I.

A FRAUD.[1]

To the Editor of THE MEDICAL NEWS,

SIR: In some of the American lay journals, especially in Cincinnati, the following misuse is made of the name of Virchow.

These journals contain an announcement that the great German physician, Dr. Karl Virchow Schiek, has just arrived from Germany and is prepared to give consultations. He claims to have made important discoveries in the germ treatment of chronic diseases, and that his prescription is used by 806 European physicians.

No physician of this name is to be found in any of the official registers of Berlin or Germany.

The intention of this man is evidently to mislead the great public by means of the name Virchow.

Yours very truly,

DR. S. GUTTMANN, M.D.,
Editor of *Deutsche med. Wochenschrift.*

BERLIN, February 11, 1892.

ORIGINAL ARTICLES.

EYE-STRAIN AND HEADACHE.

BY G. L. WALTON, M.D., AND C. F. CARTER, M.D.,
PHYSICIAN AND ASSISTANT PHYSICIAN IN THE NEUROLOGICAL DEPARTMENT OF THE MASSACHUSETTS GENERAL HOSPITAL.

THE statement in a recent editorial of the (Philadelphia) MEDICAL NEWS, that this subject has received practically no attention in Europe, and in this country only in a few cities, is undoubtedly a correct one. While the oculists and neurologists in this locality are taking up the subject with considerable seriousness, as evidenced not only in practice but in a recent contribution to the literature of the subject by Dr. Cheney (as well as in the discussion by the members of the Medico-Psychological Society, following the reading of this paper), the position of the general practitioner, taken as a whole, here as elsewhere, is probably not as yet so firmly established as experience would warrant.

In conversing upon the subject with other practitioners, we have met the usual criticisms that follow the expression of opinion in any comparatively new field. One states that the ground taken is a matter of common knowledge; the next, that it is overdrawn. In answer to the former criticism, we can only point to the literature, which certainly shows that if the knowledge of these subjects is common, its expression is singularly defective. In answer to the second criticism we have nothing to offer but facts, borne out by the everyday experience of the modern oculist, as well as to that of such neurologists as have subjected their cases to the investigation of these practitioners in preference to relying upon routine treatment by drugs.

It is a curious fact that among the causes of functional headache, and more particularly of migraine, elaborated in the various text-books and monographs, so little attention has been paid to this cause, which, in the estimation of the writers of this at least, plays a more important part than any other single factor—namely, extraneous irritation in the form of eye-strain. This is the more surprising in view of the fact that the item of etiology is generally dealt with in the text-books in a most exhaustive, though not always judicial manner; as an example of which we need only cite the disease locomotor ataxia, which is still accredited to sexual excess, exposure to cold, severe bodily and mental exertion, sudden fright and repeated anger, acute disease, as typhus, rheumatism, pneumonia and diphtheria, trauma, and tobacco, as well as to the one cause (we allude, of course, to specific disease) which can be traced in so large a proportion of cases as to render the question pertinent whether in point of fact 100 per cent. of genuine cases of the disease, after excluding Friedreich's disease, do not arise from this one poison.

It seems odd that among the long list of causes of migraine and cephalalgia, to which every collaborator adds, but from which few venture to deduct, that the one cause to which we have alluded has found so little place, scarcely more in some cases than cursory mention, in others none at all.

To cite a comparatively modern instance, the manner in which it is mentioned by Ross shows the usual lack of appreciation of the extent and character of the irritation produced by constant eye-strain. This author describes under the head of cephalalgia, the anemic, the hyperemic, the hysterical, the toxic, the febrile, the gouty, the rheumatic, the syphilitic, the neurasthenic, the organic, and the sympathetic headache, and devotes to migraine, on account of its great importance, a "separate and extended consideration." Under the causes of migraine, which is in reality one of the most common results of refractive error, this trouble is not mentioned; only under the head of "sympathetic headache" does he mention the subject of eye-strain, stating that it produces a form associated with vertigo and vomiting, referring to Weir Mitchell's article on the subject published in the *American Journal of the Medical Sciences*. The inference naturally drawn is that a certain variety of headache, of no considerable extent or importance, but characteristic in its form, results from eye-strain.

Gowers does not mention eye-strain in his otherwise exhaustive chapter on "Migraine," which he attributes to heredity, excessive brain-work, overfatigue, work in hot and crowded rooms, anemia, over-lactation, and (in one case) ague. The special treatment, he states, "consists first, in the continuous administration of drugs, and, second, the treatment of the attacks themselves"—not mentioning the necessity for the use of glasses at all. We should say rather that the first indication was to look for and to correct errors of refraction, only appealing to the continuous use of drugs as a last

resort. Certainly the patients who have tried the continuous use of drugs for years, and have finally been speedily relieved by the use of glasses, would give very decided testimony in favor of this order of procedure.

Under cephalalgia, Gowers states that a common cause of frontal neuralgic headache is the use of the eyes when there is hypermetropia, the pain going off when the use of the eyes for near work is discontinued. The misconception here is threefold—in the first place, the frontal neuralgic type of headache is by no means the only one produced by eye-strain; secondly, it is caused not only by near, but also by far work, as the action of the ciliary muscle is continuous in hypermetropia even in looking at distant objects; and, thirdly, far from disappearing when the use of the eyes is discontinued, such pain often first appears at this time. Occipital headaches are generally due, according to this author, to gastric disturbance, a point upon which we would also join issue, the pain from eye-strain being so often not only occipital, but extending down the back of the neck, that examination of the refraction seems to us in such cases indicated, rather than consideration of the digestion; and even where the latter is present, it may be secondary, as the editor of THE NEWS has pointed out, to eye-strain.

The experience of the writers, as tabulated further on, would show that after eliminating the organic, syphilitic, gouty, rheumatic, toxic, and febrile headaches described by Ross, Dr. Cheney's statement that at least half of the cases of functional cephalalgia met with in everyday practice, whether classified under anemia, hyperemia, hysteria, neurasthenia, or migraine, are curable by the adjustment of proper glasses, is by no means overestimated.

Clinicians are perhaps often thrown off the track by the statement of the patient that his eyesight is perfect, even sometimes remarkably clear. It has not infrequently happened in our experience that such patients have vision so acute for distance that they are called on by their friends to distinguish distant objects. The sufferer is in this case usually a hypermetrope, this form of refractive error being almost as potent as astigmatism in producing headache and other cerebral symptoms, on account of the constant though unrecognized effort of accommodation necessary to produce the acuity of vision which is the envy of his friends. The question of acuity of vision may, therefore, be absolutely excluded from consideration in deciding this question. It is, in fact, as Dr. Cheney has shown, often the cases in which the error of refraction is slight that cause the most trouble, as the moderate effort of accommodation here necessary to produce perfect vision is constant, whereas in cases of extreme error the effort is sometimes discontinued. It is, however, important to inquire whether there is blur before the eyes, or pain in the eyes after continued use, particularly by artificial light. It is also important to look for conjunctivitis and blepharitis, although these signs are not necessarily present. The question whether the headache occurs during or after excessive use of the eyes is also an important one to put, but the reply, if negative, is not to be too implicitly relied upon, partly because of the patient's inability to decide this point, and partly because the headache caused by eye-strain does not necessarily follow immediately upon such efforts as recognized by the patient. It may be pertinent to mention here the fact that individuals vary greatly in the amount of accommodative effort made in ordinary life, as in walking upon the street. The habit may be formed by the sufferer from astigmatism or hypermetropia of avoiding efforts at accommodation in reading distant sign-boards, telling the time at a distance, etc., by simply declining to make the effort. This habit persisted in will often relieve such a person from the necessity of wearing glasses continuously, provided he puts them on for each effort, no matter how brief, at accurate vision, as for reading or writing. For the average patient, however, it is safer to recommend the constant use of spectacles.

This variety of frame should be insisted upon at least in cases of astigmatism, if we are to do justice to the patient and ourselves; for a slight deviation of the axis may only add to, instead of relieving the irregular spasm of the ciliary muscle. This fact, added to the unnatural pressure of eyeglasses (often ill-borne) may render our endeavors futile, and lead to the supposition that the effect of eye-strain has been overestimated. It is in the majority of cases wiser, therefore, to advise the use of spectacles constantly, at least until the connection with the eye-strain is established, after which the patient, if he chooses to experiment with eyeglasses or with leaving off glasses in the street, may do so upon his own responsibility. In point of fact, however, many patients, more particularly female patients, will choose to try this experiment first, whatever is advised, and only adopt the proper course, if at all, later.

In the theater, particularly, it is important that glasses should be worn by the class of patients under consideration, the long-continued effort here necessary at accurate distant vision, by artificial light, being probably frequently the cause of the headache commonly attributed to late hours or late supper.

It is a noteworthy fact that the statement not infrequently appears in the text-books that headaches

are liable to disappear at the age of from forty-five to fifty-five, the true reason for this disappearance not being recognized, the cause being in point of fact in the majority of these cases, that the power of accommodation is lost at this age, as has been dwelt upon by Dr. Cheney in the article already quoted. The same observer points out that the usual period of onset of such headaches, namely, at the age of from twelve to seventeen years, is due to the fact that in childhood the power of accommodation is so great as to make the effort for accurate vision comparatively easy, and partly to the fact that such vision is not called for until hard study is begun. The trouble may, however, begin even in childhood, especially if the child is studious.

The experience of the writers of this paper does not bear out the statement of Ross that headache from eye-strain is particularly liable to be accompanied by vertigo and vomiting, though it may be so, nor do we recognize any constant type of headache as resulting from eye-strain, though migraine has been perhaps as frequent as any form. We have found the headache more frequently, however, beginning in the frontal and occipital regions than in the vertex or temporal regions, though all these points become involved, of course, in migraine, a form of headache in which the error of refraction is generally found to predominate on one side, or to be (in case of astigmatism) in different axes.

Ranny should certainly be given credit for his persistence in impressing eye-strain upon his readers as a cause, not only of other reflex symptoms, but also of typical migraine, which he considers invariably due to error of refraction or to insufficiency of the ocular muscles. It is perhaps the extreme character of this view that has defeated its adoption, but it is probably nearer the truth than the view that this factor need not be mentioned at all in the etiology of migraine or considered in its treatment. It would certainly be wiser to advise careful ocular examination, if necessary under a mydriatic, in the case of every sufferer than to neglect it in one case in which the use of proper glasses would give relief.

In our own practice, after eliminating syphilis, toxic influences, and organic brain-disease, an ophthalmologic investigation is the first thought that suggests itself in every case of long-standing headache, and the result has generally more than justified the investigation.

We have formulated sixty consecutive cases that we have seen in private practice, from the majority of which we have been able to ascertain the history after the use of glasses. The majority of the cases were examined either by Dr. Bradford or by Dr. Cheney; several by Drs. Wadsworth, Derby, and Chandler. The predominating refractive error was astigmatism.

The results are as follows:

Relieved	37
Relieved in a measure	5
No relief	3
Doubtful	2
No record	6
Oculist not consulted	7
	60

Among the three cases unrelieved is one in which the oculist discovered no error worthy of correction.

Three cases selected as types will serve to show the prevailing character and severity of the headache relieved by appropriate ocular treatment. It seems hardly necessary to prolong the list further.

CASE I.—A hotel clerk, about thirty-eight years old, had been troubled with severe headaches for many years, commencing in the frontal region, sometimes right, sometimes left, and extending to the occipital region. He had blurred vision at times. The attacks were frequently accompanied by nausea and vomiting, and made it impossible for him to attend to his duties for several hours. His eyes were examined by Dr. Bradford and glasses prescribed as follows:

O. U. + 0.50 S. ◯ + 0.50. cyl. ax. 0°.

Nearly two years have elapsed since he began wearing them, and during this time he says he has never suffered from headache.

CASE II.—A physician, thirty years old, had suffered with frequent headaches, generally frontal, left, ever since early childhood. These finally occurred two or three times weekly, and were not relieved by any of the usual remedies, such as phenacetin, antipyrin, etc. In the spring of 1889, Dr. Cheney examined his eyes, having first paralyzed the accommodation with homatropine. The following glasses were prescribed:

O. D. + 0.50 cyl. ax. 105°.
O. S. + 0.225 S. ◯ + 0.50 cyl. ax. 80°.

Since putting on the glasses he has had no headaches, although when he attempts to read without glasses he quickly begins to have shooting pains in the left eye and forehead.

CASE III.—A physician, aged thirty-eight, had severe and frequent headaches from the age of ten, generally unilateral, commencing in the frontal region, lasting from twelve to twenty-four hours, sometimes accompanied by vomiting, generally preceded by blurring, the latter sometimes limited to half the field of vision, the line of demarcation on one occasion being horizontal and clearly defined (exceptional). Headaches were very rare and comparatively mild since he began wearing glasses, except on one occasion after inversion of the left glass by a mistake of the optician. The statement of refractive error is taken from Dr. Bradford's notes:

O. D. = 0.8 *c* — 1.50 cyl. ax. 90°.

Eye is also myopic — 0.25, but the addition of — 0.25 causes quite severe strain.

O. S. = 0.8 *c* — 1. sp. ◯ — 0.75 cyl. ax. 45°.

The whole amount of myopia (— 1) causes much discomfort. Can bear — 0.50.

Exact refraction:

O. D. = 0.8 *c* — 0.25 sp. ⌒ — 1.50 cyl. ax. 95°.
O. S. = 0.8 *c* — 1. sp. ⌒ — 0.75 cyl. ax. 45°.

Owing to inability to use the whole amount of myopic portion of glass, the following was ordered:

O. D. — 1.5 cyl. ax. 95°.
O. S. — 0.50 sp. ⌒ — 0.75 cyl. ax. 45°.

We would not be considered enthusiasts, who, generalizing from a few cases, formulate a theory to cover all. On the contrary, we recognize all the other sources of headache enumerated in the text-books.

It must be recognized, also, that in these cases, as in all functional nervous diseases, more than one factor may be at work, all of which must be combated if perfect recovery is hoped for. An illustration of this fact is furnished by a case referred to one of us not long ago by Dr. Derby. This was in a young lady of twenty-one, who for about five years had suffered from headaches, frontal and occipital, so frequent and severe as to preclude the possibility of continuing her accustomed employment. The error of refraction had been corrected as far as possible, and some relief had thus been afforded, but the headaches persisted with a frequency of about three weekly. The patient was quite anemic, and was put upon the saccharated oxide of iron and phenacetin as required, with general directions regarding rest, exercise, and diet. Rapid improvement followed, and at the end of two months the headaches had become so infrequent, and her general health so far restored, that she was able to discontinue treatment. She only complained at that time of frontal headache of comparatively short duration and coming on only after excessive use of the eyes. At least two elements were certainly, therefore, at work in this case. It is probable that the general treatment would have proved comparatively fruitless, however, without previous correction of the refractive error, and the order of treatment adopted seems to us the rational one in such cases. This case of mixed etiology may seem an unfortunate one in this connection, especially in that the cure was not complete. We mention it, however, to show that the problem is not always a simple one, and as regards recovery, when such a delicate matter as the subsidence of a long-standing ciliary spasm is under consideration, it would be far too optimistic to expect absolute freedom from headache after the adjustment of glasses, even when the etiology is obvious; nor should the theory of eye-strain as the frequent cause of cephalalgia be challenged on these grounds, as Dr. Cheney has already pointed out.

In conclusion we would emphasize these points:

1. A large proportion of cases of functional cephalalgia, and especially migraine, is due wholly or in part to eye-strain.

2. Good vision is not inconsistent with such difficulty.

3. When practicable very slight errors of refraction should be corrected in cases of cephalalgia as well as in others with functional nervous symptoms.

ARE DIPHTHERIA AND TYPHOID FEVER FILTH-DISEASES?

By CHARLES V. CHAPIN, M.D.,
of Providence, R. I.

When, half a century ago, it began to be recognized that many diseases of an infectious and contagious nature prevailed most extensively in the midst of filthy surroundings, the doctrine of the danger of filth was preached vigorously by both physicians and laymen. This propaganda of cleanliness has been productive of so many true sanitary improvements, and throughout civilized countries has so immensely improved the comfort and decency particularly of the wage-earning class, that it has proved itself no mean factor in the civilizing influences of the age. The causative relation of filth to disease is a theory based in the first instance, it is to be feared, on the too careless inference drawn from data not sufficiently investigated and understood. That there is truth, and valuable truth, in the theory, is not to be gainsaid; but that it has often been pushed beyond all reasonable limits by its advocates must also be admitted. Our medical knowledge is a growing plant, which, while expanding in every direction, constantly needs the pruning both of its dead and its too luxuriant branches. There is usually somewhat of truth and somewhat of untruth in all the conclusions that are arrived at as the result of scientific investigation. Thus in the case of the filth-causation of disease, it is certainly true that the specific contagium of typhoid fever and cholera are contained in the evacuations of the sick, and that water and soil receiving even an infinitesimal amount of such evacuations become the storehouses and carriers of the poison. Here filth, and filth in its most offensive form, becomes the true cause of disease. But we are not warranted, therefore, in assuming that every case of typhoid fever or cholera must have its source in some vault, or cesspool, or polluted well, or that every collection of decomposing and filthy material is likely to cause these diseases. The rise of the germ-theory, when it was merely a theory, did much to strengthen popular and professional belief in filth-diseases. If filth is teeming with microörganisms, and these organisms are the causes of the infectious diseases, the best way,

and a sure way, to prevent these diseases is to get rid of all forms of filth. If a single germ, by its rapid reproduction, is capable of giving rise to a case of sickness, and if these germs can be borne on the slightest breath of air, a pin-hole opening in a sewer-pipe may be, nay, must be, a fatal opening into our dwellings for the ingress of the seeds of disease. But the labors of the bacteriologist have raised many of the propositions of the germ-theory to the realms of actual knowledge, and at the same time have shown many of the deductions of this theory to be false and misleading. Though there is plenty yet to learn, we now know enough to correct many of our former guesses. Thus we know that not all germs are pathogenic. In fact, the great majority are not, and this is particularly true of those found in decomposing material, *i. e.*, filth. In many cases, indeed, putrefactive organisms are directly hostile to the development of the pathogenic, and quickly choke them out. Thus the human alimentary tract contains countless swarms of such harmless forms. It is not filth in the sense of dead and decaying organic matter which is dangerous, but only such matter when it is the seat of growth of specific pathogenic organisms. It has also been demonstrated by inoculation-experiments on animals that the likelihood of a single microorganism, or even a moderate number of them, setting up disease, is extremely small. Practically, it is found that it requires considerable masses of organisms to insure infection, and such masses are not readily carried about in the air. Recent progress in aseptic surgery has shown that the excessive fear of aërial infection—the great bugbear of the originators of antiseptic surgery—was unfounded.

We now know, too, that microörganisms are not readily given off from moist surfaces, and that the air of drain-pipes, sewers, and cesspools usually contains a much smaller number of microbes than the air of our streets and dwellings. While "sewer air" cannot be as healthful as outdoor air, and its inhalation may produce certain constitutional and local symptoms, it certainly is not in itself the cause of infectious disease. Unless the current escaping from a leaky pipe is strong enough to carry off particles of liquid with contained organisms, it cannot be the carrier of contagion. It is extremely improbable that a small opening in a soil-pipe or drain can be the source of infectious germ-disease, even if the drain itself be infected.

Until a very recent time cholera, typhoid fever, the diarrheal diseases, diphtheria, and even malaria, scarlet fever, and smallpox, were supposed to be caused chiefly, if not solely, by filth, pure and simple. While clinical evidence has, indeed, made clear to most that diseases like scarlet fever and smallpox are probably spread by immediate contagion chiefly, yet diphtheria and typhoid fever are still commonly attributed to filth. Thus, in the last two two years, the health officers of the various towns in Michigan, in reporting outbreaks of infectious disease to the State Board of Health, found "filth," as popularly understood, the etiologic factor in the following instances: Of 251 outbreaks of diphtheria, in which the health-officer was confident enough to state the source of the disease, it was attributed to "unsanitary surroundings" in 74. In 176 outbreaks of typhoid fever in which the cause was supposed to be determined, it was attributed to filth and bad water in 76. These 76 did not include those instances in which the water was known or supposed to be specifically polluted by typhoid stools. Even 6 of 194 outbreaks of scarlet fever were attributed to filth. Nothing is more common than to have not only laymen, but also educated physicians, attempt to trace every case of diphtheria or typhoid fever to a defective water-closet, a broken drain-pipe, or a neighboring privy-vault. And nothing is more common, when such unsanitary conditions are found, than to hear exclamations of surprise that typhoid fever or diphtheria has not resulted from them. I do not by any means wish to affirm that filth is never the cause of disease, or that it is not always desirable to get rid of it if possible, nor would I belittle the work of the apostles of cleanliness who have done so much for the comfort and health of mankind. What I wish to do is to inquire whether the relation between the two diseases mentioned—diphtheria and typhoid fever—and filth is as close as is generally supposed. By limiting the agency of filth as a cause of disease to its true field, even if we do narrow it, we are aiding rather than retarding the gospel of cleanliness.

One way of determining whether the two diseases specially mentioned are caused by filth and unsanitary conditions is to find in what proportion of cases of these diseases such conditions are found in the house, and also in what proportion they are found in houses generally in the same locality. If, where typhoid fever and diphtheria are found, bad sanitation is much more prevalent than in other dwellings near by, we would have good reason for suspecting a causative relation. But if not, we would be required to seek very strong evidence elsewhere to show that these are filth-diseases. I have no data at hand for just this comparison, but I can compare houses in which diphtheria and typhoid fever occur with those in which scarlet fever occurs. As there is no evidence whatever of any relation between scarlet fever and filth, or "sewer gas," this comparison is of much value, for if we find unsanitary conditions no more numerous in typhoid and diphtheria houses than in scarlet-fever houses, we shall have on this

ground at least no reason for considering the former any more filth-diseases than the latter, and that is no reason at all. The following tables show the result of inspections of the premises where scarlet fever, diphtheria, and typhoid fever have occurred in Providence, R. I., during the last seven years. These diseases have been so evenly scattered over the city that no error can arise from one set of houses being in one section and one in another:

Results of the Examination of Premises in Cases of Contagious Diseases.

It will be seen that as regards unsanitary conditions there is practically no difference between these diseases. Thus, untrapped sinks and defective sink-pipes and drains were found in 47.3 per cent. of the houses examined in which there was scarlet fever; in 48.1 per cent. in which there was diphtheria; and in 47.6 per cent. in which there was typhoid fever. As regards privy-vaults, cesspools, and yards, nuisances were found in 12.2 per cent. of houses with scarlet fever; in 12.5 per cent. with diphtheria; and in 13.1 per cent. with typhoid fever.

There is another point worthy of notice, which indicates that diphtheria should be classed not as a filth-disease, but rather with scarlet fever as a disease caused by contagion borne from one person to another. When scarlet fever occurs in a house, the statistics of Providence show that it tends to spread from the family first attacked to others in the same house in 14.8 per cent. of the cases, and in diphtheria in 15 2 per cent. Here again the difference is too small to be of importance. As in most cases untrapped sinks, defective waste-pipes, and neighboring privy-vaults affect both tenements alike (most houses in Providence are two and one-half stories, with two tenements), we should expect to find the disease in both tenements in more than this proportion of cases if it were dependent on such conditions.

When, as health-officer, I began the study of diphtheria I was inclined to believe, as I had been taught, that it was caused in many, if not most, cases by filth; but as I have followed the natural history of the disease as it has occurred in Providence, my belief in this cause has grown less and less, and my belief in direct contagion stronger and stronger. Study of the cases shows that, as a rule to which there are not many exceptions, it appears first in a single member of a family. After that, others in the same family are taken sick at varying intervals, and in a certain proportion of cases it is afterward reported from other families in the same house. About one-half the children exposed to this disease contract it—almost exactly the same proportion as in scarlet fever. In fact, as regards contagiousness, it acts almost precisely as does scarlet fever, and the reasons for thinking the latter always contagious and never obtaining a foothold for growth outside of the body are of as much force in regard to diphtheria. On the opposite page is a tabulation of some of these facts. The data for diphtheria do not cover so long a period as those for scarlet fever, but, as about the same ratio holds for individual years, this is of little moment.

The bacteriologists have determined that true diphtheria is caused by Löffler's bacillus, and we know that this organism not only retains its vitality

for some time outside the body, thus favoring contagion, but that it can propagate itself, under favorable conditions, outside the body. We must therefore admit that dead organic matter or filth may be the source of this disease, but bacteriology and clinical evidence indicate that it is not usually so.

Typhoid fever, like diphtheria, is known to be due to a bacillus, the life-history of which has been pretty fully worked out. This organism can certainly develop outside the body, but it does not readily do so, being choked out by other forms of microbes. It is rarely found except in places which have recently been contaminated by typhoid excreta. The reasons which forbid our attributing diphtheria to the escape of sewer-air are equally good as applied to typhoid fever, and we are confronted with an additional fact that there is almost no good evidence to show that typhoid is caused by aërial infection. If it is, it must be only very rarely. It is generally, if not always, the food and drink which are the media of infection.

The tables of the results of the inspection of houses in which typhoid fever existed, as already given, are confirmatory of the view that this disease cannot be traced to defective plumbing or drainage; and they furthermore show that in the majority of cases it cannot rightfully be attributed to filthy surroundings. It has been pretty clearly proven that in a large proportion of cases typhoid fever is caused by the use of water contaminated by typhoid stools. In cities that have a public water-supply secure from such contamination, typhoid is quite rare as compared with localities dependent on wells, which necessarily offer exceptional opportunities for defilement. In cities the cases of typhoid fever that are not traceable to the water-supply seem to me likely to be caused chiefly in two ways: The disease-germs may be brought in from the country in food, as in milk, or in vegetables that are eaten uncooked, as celery, lettuce, radishes, etc. Or, perhaps, in the greater number of cases the infection may be somewhat as follows. It undoubtedly happens quite often that the discharges or the washings from soiled linen of a typhoid-fever patient are thrown into the yard or on to some refuse heap. Here the bacilli may grow for a time, and in any event, if the material becomes dry, as it often must, it may be blown away and be carried considerable distances by the wind. It is, of course, not unreasonable to suppose that food may thus be contaminated by this aërial infection. If this is a true explanation, we can say that typhoid fever is so far a filth-disease; but we must not, therefore, look for its source in the immediate surroundings. A local cleaning would not be much of a preventive, though a general removal of useless organic matter from a town or city would be.

It seems to me that diphtheria and typhoid fever are not filth-diseases, in the sense in which the public understands that term, except in a very limited

degree. Diphtheria is almost always due to contagion, though perhaps occasionally to the growth of its specific organism outside the body.

Typhoid fever is more often traced to filth in which its living cause, the bacillus of Eberth, has been growing, but usually the filth is the feces, and these are merely the carriers of the contagion. There is little or no evidence that a person contracts this disease by breathing infected air. The way of infection is by the alimentary tract.

There is little or no clinical evidence that favors, and much both clinical and theoretic that disproves, the view that sewer-air, except in rare instances, is the bearer of the infection, either of diphtheria or of typhoid fever.

TUBERCULOUS PERITONITIS FROM A SURGICAL STANDPOINT.[1]

By JOHN B. DEAVER, M.D.,
ASSISTANT PROFESSOR OF APPLIED ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA; PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC.

There is no longer any doubt that the operation of opening the abdomen, washing out and draining the cavity, is justifiable in cases of ascites not the result of disease of the liver or of the kidney, and otherwise incurable. It is also equally true that in a certain number of cases this procedure has been followed by permanent cure. But it does not follow that all cases of tuberculous peritonitis should be operated upon. The class of cases of which I shall report four does not offer a brilliant field for the operative surgeon, though much may be accomplished by exploratory incision.

The following are the varieties of the tuberculous diseases of the peritoneum:

1. Miliary tuberculosis, with ascites.
2. Tuberculous infiltration of the omentum, forming one or more masses.
3. Tuberculous degeneration of the mesenteric glands, with a matted condition of the bowel, the result of the extension of the inflammation.
4. Tuberculous infiltration of the mesenteric glands, resulting in the formation of a large tumor.
5. Abscesses of the abdominal walls, of tuberculous origin.

The causes of tuberculous disease of the peritoneum may be any of the following:

1. Part of tuberculous affections of serous membranes in general.
2. Infection from neighboring tuberculous organs, as tuberculous ulceration of the intestines, tuberculous inflammation of the glands.
3. Part of a general miliary tuberculosis, when there are no localizing symptoms.
4. Infection through the uterine appendages.

Diagnosis. The following points are to be closely observed: Family history; appearance of the individual; previous tuberculous manifestations, if any; coëxisting tuberculosis (lungs and pleura).

In the course of tuberculous disease of the peritoneum, it is not uncommon to see intestinal obstruction caused by distortions and flexions of the intestines.

When the bowel, matted together by extra-intestinal bands of tuberculous material, constitutes a mass perceptible through the abdominal walls, the size and shape of the tumor may alter remarkably within a very short time.

A mass of large size may cause pressure-symptoms, such as dysuria, icterus, dyspnea, displacement of organs, enlargement of the superficial vessels, etc.

The ascitic fluid in tuberculous peritonitis is very frequently bloody, and blood may be poured out in such a quantity as to cause all the symptoms of severe intestinal hemorrhage.

The terminations of tuberculous masses in the omentum are by absorption, and by the formation of an abscess, in connection with which there may be a fecal fistula. This abscess may also perforate the gut and be evacuated in that manner.

The report of the following cases may serve to illustrate some of the foregoing points:

Case I.—Mrs. U. V., white, forty-eight years of age, was admitted to the German Hospital, September 3, 1889, with her abdomen much enlarged. She had a family history of tuberculous disease. The present trouble, of some months' standing, commenced with pain in the abdomen, which was at first severe in character, but since the abdomen had commenced to enlarge it had been less severe. Physical examination showed the cavity distended with fluid. Examination of the chest and urine was negative.

Prolonged medical treatment having proved of no effect, I opened the abdomen in the middle line and evacuated a large quantity of bloody liquid. Both the parietal and visceral layers of the peritoneum were studded with miliary tubercles. The abdominal cavity was washed out thoroughly with warm distilled water and drained. The patient was discharged cured December 6, 1889. The cure was practically brought about at the end of five weeks after the operation, but in order to see if there were any tendency to a recurrence of the dropsy, she was detained in the hospital until the date of her discharge.

Case II.—J. R., thirty-eight years of age, was admitted to the German Hospital with a history of two sisters having died of pulmonary tuberculosis. There was no other discoverable hereditary taint. One year and a half before admission he received a heavy blow in the right iliac region, and this was followed by pain and tenderness lasting for many months. Six months before, he had had acute peritonitis, and one month after recovery from this, a second attack followed.

[1] Read before the Philadelphia Academy of Surgery, March 7, 1892.

Six weeks before admission he was seized with severe colicky pains in the abdomen; these, with tenderness in the iliac region, persisted until the case was treated surgically. He has always been somewhat constipated. He had no history of caseating cervical glands or of other tuberculous manifestations.

The patient on admission was emaciated and anemic, and complained of severe paroxysmal pain in the umbilical and right iliac regions, the abdomen being distended and tympanitic, the bowels confined. Physical examination disclosed a fluctuating tumor above and to the left of the umbilicus, the surrounding structures being prominent and reddened. There was no demonstable tuberculous disease of the pleura or of the lungs. A small quantity of pus escaped from an opening below the umbilicus.

The patient's abdomen was smeared with belladonna and mercury ointment, and he was tentatively treated for some time with alteratives and laxatives. The bowels moved freely, but the subjective symptoms did not lessen in severity, nor did the lumps in the abdomen diminish in size.

It was decided to explore both the fluctuating tumor above the right groin, and the abdominal cavity above the umbilicus, near the site of the non-fluctuating mass. Incision into the swelling above the groin evacuated a small quantity of cheesy pus contained between the transversalis muscle and the transversalis fascia. The wound was packed with iodoform gauze. Incision through the linea alba into the abdominal cavity above the umbilicus evacuated a puriform liquid from a cavity between the posterior layer of the sheath of the left rectus muscle and the transversalis fascia, and revealed a growth of considerable size involving the great omentum. It being impracticable to remove this infiltrated tissue, the wound was packed with iodoform gauze, the gauze in this instance being placed in direct contact with the coats of the intestines, since the edges of the parietal peritoneum could not be approximated.

Since the operation the patient has steadily regained flesh and strength, and the new-formed tissues have been entirely absorbed. He was discharged six weeks after the operation, cured.

Case III.—Frank K., white, twenty-eight years of age, referred to me by Dr. C. Marshall, had been suddenly seized with colicky pain that had persisted for six weeks before his admission to the German Hospital. He could give no family or previous personal history of tuberculosis. He had never suffered from severe constipation, but his bowels had always been somewhat confined. The abdomen was hyper-resonant, except in the right hypochondrium, where there was distinct dulness. Palpation revealed a fixed, regularly nodulated tumor, extending to the right as far as the median line; below to one inch beneath the level of the umbilicus; and above to within one inch of the lower border of the tenth rib; its left border was undefined and apparently more deeply seated than the other portions of the growth. There was no ascites, and the contents of the thoracic cavity were normal. The patient was markedly anemic, and had lately lost several pounds in weight. His temperature was constantly somewhat elevated. The growth varied considerably in size and shape from day to day, a peculiarity explained by Goodhart by the fact that these masses usually consist of intestines matted together by intestinal bands of tuberculous material.

The patient's grave condition improved somewhat during his stay in the hospital. He would not consent to an operation. I believed the growth to be tuberculous. I advised an exploratory laparotomy for a twofold purpose: first, to determine definitely if the mass was matted bowel or omentum. If the former, I proposed to attempt to separate the adherent coils, irrigate, and drain; and if the latter, I hoped, if feasible, to remove the mass.

On January 2, 1892, the case was again admitted to the hospital, willing now to be operated upon, because while away he had grown much worse. Laparotomy was performed, and after the escape of several ounces of milky fluid there was seen a nodulated growth involving the spinal attachment of almost the entire mesentery. A nodule at one point of the growth presented a decidedly yellow appearance, suggesting commencing degeneration. The intestines were intact. From the size and situation of the growth, removal was not attempted. The abdominal cavity was thoroughly irrigated with warm distilled water and drained. Drainage was kept up for two weeks until there was no longer any discharge. The fluid drained off for the first two or three days was like that evacuated at the time of the operation, namely, milky, and apparently largely composed of chyle. An examination of the fluid did not determine definitely the presence of chyle. After the third day the discharge was lighter in color, and so continued until it ceased to flow. Death from exhaustion occurred on February 8, 1892.

An autopsy permitted upon the abdominal cavity showed only a large quantity of milky fluid, and the tumor (mesenteric) I here exhibit. The peritoneum was much injected and thickened.

Case IV.—Willie C., white, seven years of age, referred to me by Dr. J. V. Kelley, of Manayunk, was always an unusually healthy child until one year ago. He had never shown any personal manifestations of tuberculosis, but presented a somewhat significant family history, his maternal grandmother having died of pulmonary tuberculosis. His illness began with a contusion of the abdomen received while sledding. He subsequently complained of severe pain about the umbilicus. His parents could discover no local lesion, and thought he was malingering to escape going to school. His distress, however, became so unfeigned and severe that Dr. J. V. Kelley was called in, and he at once discovered a mass in the abdomen near the navel. Poultices were applied for some months, and although the little patient was still able to play about as before, he continued to complain of pain. The tumor remained stationary until four months ago, when pointing occurred at the umbilicus, and a considerable abscess discharged itself. A purulent discharge has since persisted, which one month ago became distinctly fecal in character. Since the appearance of feces

at the umbilicus the boy has progressively lost flesh and strength; a chronic diarrhea has set in, the stools being illy formed, dark, and excessively offensive. A doughy non-sensitive mass is still demonstrable in the umbilical region.

There is no reason why local tuberculous deposits, if they can be made out, and are in a convenient situation for operation, should not be removed before the trouble becomes general.

In suppurative cases, when the pus is confined, laparotomy should at once be performed, the abscess-cavity opened, washed out, and drained.

Case I was one of miliary tuberculosis of the peritoneum, with ascites.

Case II was an example of abscess of the abdominal walls associated with a tuberculous tumor of the great omentum. The operation of laparotomy served to evacuate the pus, which occupied the transversalis fascia, and which had evidently found its way thither from the omental mass. Packing the wound with iodoform gauze both medicated as well as drained the peritoneum at the most pronounced seat of the disease. Owing to the extensive adhesions, I did not think it prudent even to attempt to remove the omental tumor.

Case III was one of tuberculous disease of the mesenteric glands in its early stage.

Case IV was one of tuberculous infiltration of the omentum, terminating in suppuration, with bowel-involvement (fecal fistula). Here operative measures are contra-indicated.

To Dr. J. C. Heard, my resident surgeon at the German Hospital, I am indebted for the notes of the cases reported, and for his care of the patients.

HEMORRHAGE INTO THE CORD, WITH REPORT OF A PROBABLE CASE.[1]

BY G. J. PRESTON, M.D.,
PROFESSOR OF PHYSIOLOGY AND DISEASES OF THE NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE.

IN speaking of hemorrhage of the spinal cord it is necessary to distinguish between hemorrhage into the membranes and hemorrhage into the substance of the cord itself. The former—meningeal hemorrhage—is more frequent, and may be either extra-dural or sub-dural. The latter variety—hemorrhage into the substance of the cord—is the one that forms the subject of this paper.

So rare is hemorrhage into the cord, and so few have been the post-mortem examinations, that many neurologists deny the existence of such a condition. Charcot, among others, holds that primary hemorrhage is rarely, if ever, encountered, and that there is always a preëxisting inflammation, so that what has been called hemorrhage is really a very acute hemorrhagic myelitis. While undoubtedly many of the cases reported as primary hemorrhage were in reality cases of myelitis, still there have been a few cases, completed by autopsy, that would seem almost conclusive. One great difficulty is that in most of the cases that have come to autopsy the patients have lived long enough to allow a myelitis to supervene upon the extravasation of blood—a necessary consequence when we consider the proneness of the cord to inflammation. Throwing out, then, the doubtful ones, we still have enough cases, it seems to me, to fix hemorrhage into the cord as a pathologic entity.

It is not an easy matter to explain why hemorrhage into the cord should be so vastly more infrequent than hemorrhage into the brain. The only explanation that can be given is that the arteries that supply the spinal cord have, generally speaking, a long and tortuous course, and are not so liable to feel changes in blood-pressure as are the shorter and more direct cerebral vessels. The branches from the vertebrals and the branches from the intercostal and lumbar arteries are, for example, far less exposed to the risk of rupture than the middle cerebral, because they are not in the line of force, as is the cerebral. Most observers have denied the existence of aneurismal dilatations of the spinal arteries, so common in the cerebral vessels. There would seem, then, to be no predisposing cause, such as we have in cerebral hemorrhage.

In considering the general etiology, the data are yet too few and uncertain to allow any very certain conclusions to be drawn. We leave out, of course, that most common cause—traumatism—since we are speaking of idiopathic hemorrhage. Violent exertion, sexual excess, certain fevers, as smallpox, typhus, and typhoid; scurvy, tetanus, convulsions, strychnine, alcoholism, suppression of the menses—these are some of the causes that have been thought to have more or less influence in bringing about the condition. The blood may appear as minute points, scattered mainly in the gray matter, since this part of the cord is more richly supplied with blood, and the walls of the vessels have less support than in the white matter; or we may have a very considerable quantity of blood poured out, causing great destruction of nervous tissue. Judging from certain distinctly marked cases, clinically, which recovered, it is probable that small extravasations may be quickly absorbed and may do no great damage.

Cases have been encountered at all ages, though perhaps the accident may be said to occur most frequently in males between twenty and forty years of age.

The symptomatology will necessarily vary with the amount and situation of the hemorrhage. A

[1] Read before the Clinical Society of Maryland, January 15.

large amount of blood, or even a small quantity, in the upper cervical region, may prove very rapidly fatal. The most important symptom is the suddenness of onset. If there are distinct prodromata of some days we must call the case one of myelitis, and not hemorrhage—at all events a *myelitis hemorrhagica*, and not idiopathic hemorrhage. Pain is not as common nor as severe as in meningeal hemorrhage, but it is usually felt at some point along the spine, with perhaps some girdle-sensation.

The patient in a few moments loses strength; if the hemorrhage be in the cervical region, a more or less general paralysis occurs; if in the dorsal or lumbar region, paraplegia. There may be some hyperesthesia, but this rapidly passes into anesthesia, which corresponds to the segment of the cord involved. There is an absence, or at least there is very little of the spasmodic movements and muscular rigidity, so characteristic of meningeal involvement. Of course, the meninges may be to some extent involved in an intra-spinal lesion, and hence we may have symptoms of both conditions. Bladder and rectum may be involved, especially when the lumbar cord is the part affected. There may be slight loss of consciousness, but rarely is this symptom marked. Respiratory and circulatory disturbances, as well as pupillary disturbances, are the rule when the hemorrhage is in the upper cervical region. It is important to observe that there is never any rise of temperature. The reflexes are likely to be slightly exaggerated unless large areas of gray matter, as the lumbar enlargement, be involved, in which event, of course, they are abolished.

No very thorough electrical tests seem to have been made, but in all probability electrical reaction is not much altered, unless the gray matter be largely destroyed. In this case we have either entire loss of electrical reaction or the reaction of degeneration. Muscular atrophy follows destruction of the gray matter; otherwise contractions may be noticed.

The foregoing, in brief, are the more salient points in the symptomatology of this rare affection. The following case, which came under my care recently, presents, I think, enough of these symptoms to warrant a diagnosis of hemorrhage into the cervical portion of the cord.

J. C., thirty-three years of age, a blacksmith, with a family and personal history remarkably good, says that he has never been sick a day in his life. He is a large, healthy-looking man. Three weeks before admission into the hospital he arose in the morning feeling perfectly well, ate a good breakfast, and started to his work. After walking a short distance he felt a sudden dizziness, with sharp pain in the cervical region, and he fell to the ground. He was not unconscious. He suffered more or less pain during that day, and on the next day the pain in the region of the seventh cervical vertebra was very sharp. When he was picked up, after he had fallen, he was entirely helpless—not able to move hand or foot of either side; he was not able to move his hand freely, though he had no aphasia or facial paralysis. There was tenderness on pressure over the cervical region. He says there was marked loss of sensation, especially in the arms.

He has now regained slight use of arms and legs; he can feed himself and walk with assistance, but he has little or no use of his fingers for nice movements. There is no atrophy of muscles, or at all events atrophy is not marked. The patellar reflex is about normal. There is loss of sensation over the outer side of both arms; sensation in the legs is normal. There is slight stiffness of the neck. There is decided tenderness to deep pressure over the seventh cervical vertebra. The general condition of the patient is good. Neither bladder nor rectum is affected. The muscles of the arms showed increased reaction to the galvanic current — what might be called a slight reaction of degeneration.

The patient only stayed a week in the hospital, and has never returned, so that the outcome of the case cannot be given.

The sudden onset of the attack, while the patient was in perfect health, the absolute paralysis, the loss of sensation, the electrical reaction, the local pain—all point to hemorrhage into the cord.

Curiously enough, there was in the surgical ward of the hospital at the same time a case of fracture of the spine at about the seventh cervical vertebra, afterward confirmed by autopsy, and the areas of anesthesia of the two cases corresponded almost exactly. In all probability, as the case went on, muscular atrophy of the arms developed, an event that was foreshadowed by the electrical reaction.

CLINICAL MEMORANDA.

A CASE OF SO-CALLED LARYNGEAL VERTIGO OR LARYNCEAL EPILEPSY.[1]

BY WENDELL C. PHILLIPS, M.D.,
ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, THROAT DEPARTMENT, NEW YORK.

OF the various neuroses of the larynx none is so rare or so unique in characteristics as that described as "laryngeal vertigo," "laryngeal epilepsy," and "complete glottic spasm in adults." So few cases of the affection have been reported that it would seem to be the duty of observers to report such cases as may come under their care, and for this reason I take occasion to add another history to the list.

Lennox Browne is the first to mention the disease in any work on *Diseases of the Throat*, but it was first

[1] Read before the New York Academy of Medicine, February 18, 1892.

described in 1876 by Charcot.[1] Since that time cases have been reported by Gasquet,[2] Krishaber,[3] Grey,[4] Lefferts,[5] McBride,[6] Russell,[7] Massei,[8] Thermes,[9] Knight,[10] Gleitsmann,[11] Dauvan,[12] Lenox Browne,[13] Armstrong,[14] and recently a case has been reported by Adler.[15] About twenty-five cases in all have been reported.

The history of my case is as follows: W. J. R., aged fifty years, an Englishman, manufacturer of confectioners' supplies; has resided in America ten years. His family history is good; his father and mother are still living and free from neuroses, and five brothers are all in good health. His complexion is florid and his appearance robust. He has never had venereal disease, and careful examination reveals no symptoms of syphilis, either inherited or acquired. He is of nervous temperament but has never developed any neurotic characteristics, but says his friends call him excitable. For ten years he has been under severe mental strain, from business worriment. One year ago he had articular rheumatism for four days, this being his only attack. He has never had muscular rheumatism or gout. He never has used tobacco or snuff in any form, but takes ale or beer in moderation with his meals.

In July, 1891, on entering a shop, he stepped into an open trap-doorway and struck on his hip. He was badly stunned, but did not lose consciousness. He was in bed only eight days, but refers all his suffering to the hip, and says that though he was very nervous he had no disturbance referable to the head and spine during that time. Aside from this, he has never had any fright or sudden shock of any kind; neither has he had convulsions or fits. He has never had vertigo in any form, but has had what he calls bronchial catarrh for several winters. His eyesight and hearing are normal, and he has never had aural vertigo. He has had headaches quite frequently during his life, but less so now than formally, and has never been annoyed by hebetude or mental confusion. His attacks of coughing have always been accompanied by a profuse discharge of frothy mucus, which was on one occasion tinged with blood. Physical examination reveals very little, except coarse râles, but his heart is slightly hypertrophied and its action weak.

He first came under my notice December 20, 1891. Three weeks previously he had taken a cold that had followed about the course of those of previous years, until one week ago, when the cough became more violent and paroxysmal. He remarked to me that it was "like whooping-cough, because it was so strangling." Two days before I saw him, during a paroxysm of coughing, without premonition of any kind, he fell suddenly to the floor upon his back, entirely losing consciousness. The attack lasted but a few seconds; he arose from the floor feeling perfectly well, with no pain or unpleasant feeling of any kind, and with no vertigo either before or following the attack. The sensation was exceedingly pleasurable, and upon being asked how he felt after an attack, exclaimed "I felt as though I had been in heaven."

Following the first attack he had one nearly every day for four days; they sometimes occurred while he was in bed. As a rule, he stood up when coughing and leaned forward with his hands upon a chair or some other object for support, but he invariably fell upon his back during the attack. On one occasion he fell upon the street, but was up again before anyone reached him. In every instance the loss of consciousness came on during a paroxysm of coughing, but he had many paroxysms of cough which were not followed by loss of consciousness. He had had four when I first saw him, and loss of consciousness was complete in all, and the sensation that gave rise to the cough was the same as he had experienced in former years. He did not bite his tongue, foam at the mouth, or groan or shriek; but on several occasions his mouth twitched convulsively during the attack, and his eyes remained open. He had, in all, twenty fits, and on one day he had five fits between 3 and 9 P.M. In every instance there was complete loss of consciousness. I instructed his wife to watch him carefully during the attacks; she reported that his face became very blue, and that unconsciousness would terminate in from five to fifteen seconds, when he would arise and walk as steadily as before. On two occasions he complained of a sensation of pressure in the arms and in the region of the deltoid muscle, and, again, of what he termed "smarting of the brain." The patellar reflexes were normal.

Examination of the upper air-passages revealed a general hyperemic condition with no specially sensitive areas. There is polypoid degeneration of the middle turbinated bones, an exostosis on the septum, on the right side, with a posterior hypertrophy on the right inferior turbinated bone. There is no varix at the base of the tongue and only slight hypertrophies. His uvula was amputated thirteen years ago on account of its relaxed condition, which caused cough. The larynx, aside from a subacute inflammation, is normal in appearance. The vocal cords are congested at the edges, but approximate perfectly. There are no signs of paralysis.

After about ten days' treatment these attacks disappeared entirely, and have not recurred up to this time (February 18th). His diet was carefully regulated, his bowels opened with a brisk cathartic, and he was given fifteen grains of bromide of sodium, three times a day, in conjunction with five-minim capsules of eucalyptol, four times a day. The eucalyptol relieved both the cough and the profuse discharge in a very few days, and he has made a good recovery. He had no other medicine except a general tonic.

Lefferts's paper, published in 1883, closes with this suggestive statement: "Have I not said enough concerning this rare and curious affection to show, first, what a field for speculation, thought, and investigation lies

practically before us; and, second, should not this thought stimulate us to the task?" Nearly a decade has passed, during which careful observers have published cases that have come under their care, and all have noted the same general run of symptoms, viz: Paroxysms of cough, cut short by sudden loss of consciousness of short duration, occurring always in adults, and without premonition, leaving the patient as well as before the attack. In most cases there was a neurotic predisposition.

These symptoms could hardly be associated with any disease—so that the diagnosis is easy. But observers vary greatly as to the name that this disease should receive. So far, the consensus of opinion favors epilepsy.

Grey says: "The term vertigo seems to me to be a misnomer for these cases, in all of which consciousness was entirely lost, and in many of which there were convulsive movements. They are notably unlike the vertigo of Menière." This is exactly opposite to the views held by Charcot. Others, including McBride, Russell, Knight, and Gleitsmann believe it to be due to disturbance of the circulation of the brain. Lennox Browne inclines to Grey's opinion that the attacks "are more in common with the milder forms of epilepsy than with simple vertigo." McBride gave it the name "complete spasm of the glottis in adults." Thus, different observers have seen fit to give this condition different names, but no name has yet been suggested that conforms to the opinions of all observers. It would seem to me that the absence of vertigo in so many of the cases would preclude the use of the word as a name for this condition—while epilepsy would more nearly fill the requirements. Laryngeal syncope might be suggested, inasmuch as the condition is a "sudden loss of motion and sensation," with a certain amount of disturbance of the circulation and cessation of respiration. On the other hand, the pleasurable sensations experienced by so many of the patients might be accounted for by asphyxia on the same principle as that produced by laughing gas—a thought suggested to me by a prominent neurologist.

A word as to treatment. I have regretted that I did not confine my treatment to eucalyptol, so that I might have demonstrated its effects in a case of this kind. Its well-known influence upon cases of chronic bronchitis, both for the reduction of cough and diminution of expectoration, would seem to give us a remedy that will strike at the root of the disease. I cannot say too much for this remedy, given internally, for all cases of nasal, laryngeal, and bronchial affections when accompanied by free discharge. Its superiority over the eucalyptus oil can easily be demonstrated.

THE REMOVAL OF THE FAUCIAL TONSILS BY THE GALVANO-CAUTERY SNARE.[1]

By HANAU W. LOEB, A.M., M.D.,
PROFESSOR OF DISEASES OF THE NOSE AND THROAT, MARION-SIMS COLLEGE OF MEDICINE; SURGEON, NOSE AND THROAT DEPARTMENT OF THE GRAND AVE. FREE DISPENSARY; LARYNGOLOGIST TO THE MISSOURI PACIFIC HOSPITAL, ST. LOUIS, MO.

It is not contended that the removal of the hypertrophied faucial tonsils by the galvano-cautery snare is a new discovery. It simply suggests that the writer feels morally sure that the members of our profession have been slow in appropriating a most valuable expedient and one that, as it were, glared them in the face. However, the basis of what may well be termed the ideal method of tonsillotomy dates back many years and its elaboration has been the result of gradual growth.

Perhaps the excision of the tonsil by the cold snare, so often given to the young and eager students in nose and throat diseases as their first lesson in tonsillotomy, constitutes the *pater bonus* of the galvano-cautery snare operation, just as in the removal of nasal polypi it was the origin of the more scientific method that supplanted it. Very naturally, the tediousness of the operation and the prolonged continuance of the pain militated against its universal adoption; besides, the use of the tonsillotome was so easy and satisfactory that no one cared to exert the patience that was entailed by this method—a refinement of art with few advantages and with many unsatisfactory features. But the application of galvano-cautery to the wire changes the argument of the case, relieves the snare of the onus of tediousness, and adds to its advantages so many improvements that, after once being used, it will be advocated in every favorable case. And the fact that it is not generally adopted can only be explained on two grounds: either the profession at large is not conversant with the operation—for, indeed, little has been written upon the subject—or, true to the immemorial traditions of medicine, the profession is loth to give up an operation that answers the needs so well, even if it is not ultra-scientific.

Comment is almost unnecessary upon the shortcomings and advantages of the tonsillotome; it is a serviceable instrument, and beyond the little annoyances of a possible uncleanliness of the instrument, the dangers of hemorrhage, and of snipping off a piece of the palate, and the necessity of frequently operating, as it were, with the eyes closed, the instrument is more or less perfect.

The good effect of such an operation, too, is dependent upon the operator, and we thus have every possible gradation between those who operate in the hit-or-miss style and those whose surgical technique is so finished that they can remove just as little or just as much as they desire with the utmost ease. It will be admitted, however, that in a great number of cases one is not able to remove precisely as much of the tonsil as he desires; so that there is at least room for some improvement in this particular. Again, the very common practice of pressing the tissues below the ramus of the jaw inward, augments whatever dangers otherwise existed. Any abnormality in the arrangement or course of the bloodvessels in this region may, under such a practice, change a benign operation into a dangerous one.

In the galvano-cautery snare, we have an instrument which overcomes even these little deficiencies. The danger of infection is reduced to a minimum, since it is a self-sterilizer; the red-hot wire consumes whatever germs are in contact with it, and by searing the exposed tissues prevents, in part at least, the possibility of septic infection. No hemorrhage results even in adults, and thereby an important danger is avoided. In this connection it may be remarked that although the statement is going the rounds that there has been no authentic case of fatal hemorrhage from the use of the tonsillo-

[1] Read before the St. Louis Medical Society, Dec. 12, 1891.

tome, it is, however, certain that distressing and even alarming bleeding does occur which would be impossible in a cautery operation.

The operation advocated does not necessitate the exercise of what Mackenzie describes as the only brute force required in any operation upon the throat. Again, there is no possibility of cutting off or injuring a portion of the palate. Finally, the operation is a scientific one which insures precision and security. Each operator may decide for himself how much of the tonsil he desires to remove, and what is still better, he can remove exactly that amount. In my own practice I have been so struck with the satisfactory results of this method that, where it is possible to do so, I now use it to the exclusion of all others; in fact, the considerable experience of ten months with the method amply confirms my original impressions and my present position.

The instrument used is the ordinary galvano-cautery snare for the removal of nasal polypi, consisting of a platinum or an irido-platinum wire about the size of a No. 5 piano wire, which is passed through two hollow tubes and is attached to a slide for tightening the loop. While there might appear to be some difficulty in engaging the tonsil, this will be obviated by adopting the expedient of pulling out the tonsil from its palatal bed with a pair of single-pointed forceps. Once engaged, the process is simple: drawing the wire tight by pulling the slide and sending the current through it, the operation, with but slight pain to the patient, is accomplished in a moment. It is well to make an application of a 5 or 10 per cent. solution of cocaine to the tonsil and the subjacent mucous membrane, so that the patient will not be conscious of the presence of the wire as it is being placed around the tonsil. Intra-tonsillar injections may be made, but thus far I have not found it necessary to do this. A two-celled storage battery of almost any manufacturer is sufficiently powerful for the performance of this operation. I have used the Meyerowitz storage battery with perfect satisfaction. Of course, many will be inclined to harp upon the unreliability of batteries and upon the careful attention they are supposed constantly to require; but, nowadays, when storage batteries are so elegantly made, no such condition of affairs need obtain.

The removal of the hypertrophied tonsils by galvano-cautery snare is indicated above all others whenever there is any tendency to hemorrhage; in fact, whenever there is any possibility of serious hemorrhage occurring; hence it is especially advisable in adults.

When removal of adenoid growths in the vault of the pharynx is to be done simultaneously with excision of the tonsils, nothing can take the place of the operation that I advocate. And for this reason: when the tonsillotome operation is performed first, the bleeding may prevent the removal of the adenoids, and if the latter is performed first too much hemorrhage almost invariably supervenes to permit the former. By using the galvano-cautery snare, both operations may be completed without the occurrence of tonsillar hemorrhage and the subsequent anesthesia, and operative interference will not be necessitated.

Even in tonsils that are more or less impacted, or over which the anterior pillar projects to any extent, can this method of procedure be utilized. For it is easy enough to grasp a small portion of the tonsil with forceps, to engage the snare, and then to remove the tissue. On a number of occasions I have had the satisfaction of observing the atrophy of the tonsil succeed this operation, with disappearance of the previous symptoms. It is certainly better to remove in this way a small portion of the tonsil than simply to cauterize it, for in the former case we have all the advantages of cauterization with the added feature of removal of a portion of redundant tissue. This is better in many instances, to my mind, than dissection of the impacted tonsil, whether by galvano-cautery or otherwise. At any rate, it is advisable to attempt the removal of a part in this way, previously to undertaking the more complicated and serious operation of dissection.

Dr. Jonathan Wright has devised an instrument for the removal of tonsils by galvano-cautery, which may be described as the application of the galvano-cautery principle to Mackenzie's guillotine tonsillotome. While the instrument is doubtless of considerable service, it presents no advantages over the simple snare, and it is far more complicated.

Up to the present time I have not met with any complications resulting from this operation. On a number of occasions I have observed some little ear-pain immediately following the operation and sometimes persisting for a short time thereafter. This I have thought was due to the too great traction made upon the palate.

Anesthesia is not more frequently required for the performance of this operation than for the older method. In fact, it has seemed to me that it was easier to get the child's consent than when I removed the tonsil in another manner. In a number of cases, children have not only submitted to the operation but have also allowed it to be done before a large class of students.

PROFESSOR WINCKEL'S ANTERIOR COLPORRHAPHY.

BY THEOPHILUS PARVIN, M.D.,

PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN IN JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

THIS operation is described in a paper by Dr. Winckel in the *Münchener med. Wochenschrift*, No. 31, 1891. Two illustrations are given with the description.

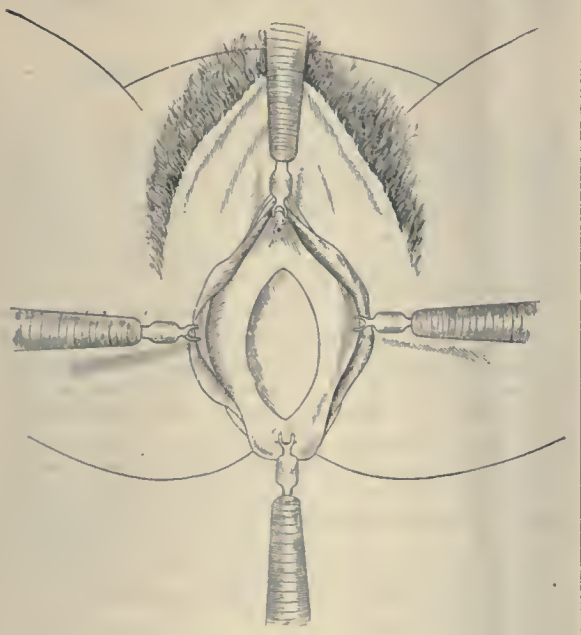
The operation commends itself by its simplicity, by its being comparatively bloodless, by there being no sacrifice of tissue, and by its satisfactory results in its author's hands. The operation has been done by me only once, and this too recently to know the ultimate result, but Dr. Winckel's experience justifies presentation of the method to the American profession.

The second and third illustrations are in part copied from those of the author, but, as I believe, somewhat improved, while the first is original. For the three as they now appear I am indebted to Dr. Bert L. Swayze.

The first illustration shows the field of operation properly exposed, and the surface made level by pulling moderately upon the four tenacula. It will be observed that these tenacula are near the extremities of the two diameters of an ellipse. The figure also shows an ellipse

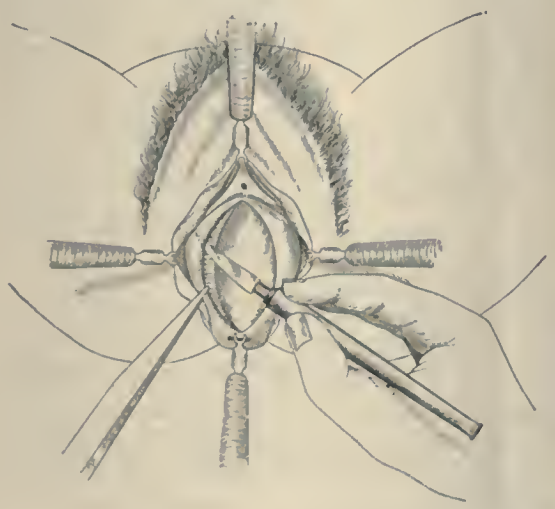
circumscribed by a vertical incision through the mucous membrane.

Fig. 1.



In the next illustration there is seen the dissection of a flap circumscribing the incised line.

Fig. 2.

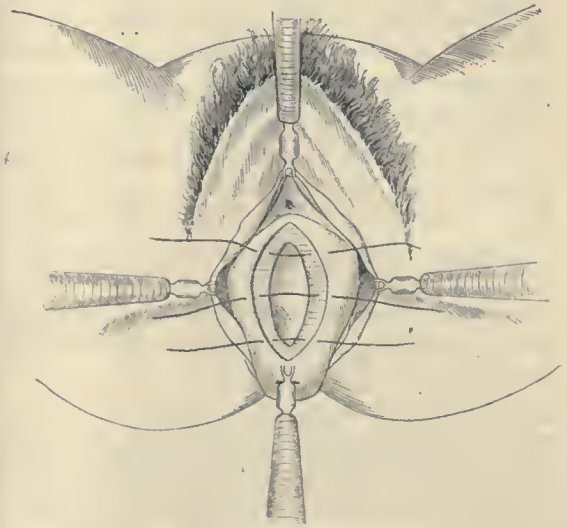


Next, the inner surface of this circumscribing flap is brought together by three silkworm-gut sutures. Fig. 3 shows these sutures introduced, but not tied.

After these sutures are tied, a continuous catgut suture is introduced, and the operation is ended.

When one bears in mind that in most, if not all, the cases in which anterior colporrhaphy is required, the vesico-vaginal wall has been greatly thinned, there is reason to believe that that mode of operating will be best in which no tissue is sacrificed, but rather retained, so as to assist in restoring the normal thickness of that wall, and especially at that part which has become thinnest, viz., that which is furthest from the point of attachment. It is readily seen that, from the extent of

Fig. 3.



surface brought together in the median line, this part of the wall is made especially strong and resistant.

MEDICAL PROGRESS.

Acute Angio-neurotic or Circumscribed Cutaneous Edema.—Bauke (*Berliner klin. Wochenschr.*, 1892, No. 6, p. 114) reports two cases of angio-neurotic edema—one in a female, the other in a male. From these and from a summary of the literature, he finds many reasons for a belief in the purely nervous nature of the affection. In most of the cases the patients have been neurotic, some presenting hereditary tendencies. In many the condition was associated with other neuroses, such as urticaria, neuralgia, abnormal sensations, digestive derangement The swelling of the skin commonly set in abruptly after mental or emotional perturbation, and disappeared as suddenly; sometimes it appeared to depend upon alcoholism. It is usually unilateral in distribution, and in females its occurrence is favored by the menstrual or the climacteric period. Its cessation is dependent upon the improvement and removal of the nervous condition with which it is associated.

Double Hemorrhagic Subdural Cyst.—At a recent meeting of the Pathological Society of London, Pitt (*Lancet*, No. 3558, p. 1042) presented a double hemorrhagic subdural cyst, obtained from a man, aged forty-six years, who for eighteen months had suffered with frontal headache, with occasional right-sided twitching at night. The twitchings became more frequent two weeks before death, when the man became dull, apathetic, and increasingly comatose. At the autopsy, two delicate cysts were found in the subdural space in the frontal region. The walls of the cysts were composed of embryonal connective tissue. The cyst on the right contained six ounces, that on the left three ounces of serous fluid and recent blood-clots. The dura mater was not inflamed.

The cysts were loosely attached to the dura mater, but not to the arachnoid.

Unusual Causes of Jaundice.—WHITE (*British Medical Journal*, No. 1622, p. 219) has reported the fatal case of a man eighteen years old, who, following an attack of right-sided pneumonia, successively developed hectic temperature, jaundice, and the symptoms of empyema. At the autopsy a ruptured aneurism of the right branch of the hepatic artery, as large as a Tangerine orange, and compressing the hepatic duct and portal vein, was found. A smaller aneurism occupied the left hepatic artery.

In the case of another man, thirty-four years old, jaundice appeared, and the urine contained biliary pigment in conjunction with the existence of a movable right kidney; a corrective operation upon which was followed by disappearance of the symptoms.

A Mechanical Aid in Cases of Paralysis of the Radial Nerve.—To make good in some measure the loss of power in the extensors of the hand and fingers, with the consequent loss of function in the unantagonized flexors, HEUSNER (*Deutsche medicin. Wochenschr.*, 1892, No. 6, p. 115) has constructed a device by which the hand is maintained in a position of normal extension. The carpus, the wrist, and the lower half or two-thirds of the forearm are encased in a leather frame, reinforced on its flexor aspect by a steel plate. The thumb is left free. Upon the extensor aspect of the casing, toward its radial margin, provision is made for the attachment of four wide rubber bands that run through stalls on the dorsum of the carpus and are attached to other rubber bands encircling each finger at its origin.

The Prophylaxis of Ophthalmo-blennorrhea Neonatorum.—BRISKEN (*Münchener medicin. Wochenschr.*, 1892, No. 5, p. 67) defends the utility of the method of Kaltenbach in the prophylaxis of ophthalmo-blennorrhea neonatorum, consisting in vaginal antiseptic douches at the beginning of labor, together with washing of the eyelids of the infant with distilled water immediately after birth. Among 728 cases thus treated, during a period of nearly three years, at the Frauen-klinic at Halle, there was not a single instance of ophthalmo-blennorrhea at birth.

The Etiology of Paretic Dementia.—In observations made at the Vienna Insane Asylum, OBERSTEINER (*Internat. klin. Rundschau*, 1892, No. 4, p. 137) found that about a third of those presenting various forms of paralysis were syphilitic, while of these seven-eighths were paretic dements. Of other forms of psychosis but 3 per cent. presented a syphilitic history. That the relation between syphilis and paretic dementia is a direct one seems demonstrated by the identity of the lesions in the nervous system and those in other organs.

Uterine Complications of Influenza.—In addition to cases of hemorrhagic endometritis, in conjunction with influenza, already reported, GOTTSCHALK (*Centralbl. f. Gynäkol.*, 1892, No. 3, p. 49) reports two cases in which the onset of the disease was marked by profuse uterine hemorrhage, while in its further course parametritis, with exudation, appeared. In a third case, at the beginning of an attack of influenza, an acute parametritis was developed in connection with preëxisting parametrial adhesions.

THERAPEUTIC NOTES.

Exalgin in Chorea.—LOWENTHAL (*Berl. klin. Wochenschr.*, 1892, No. 5, p. 95), reports the results of the employment of exalgin in the treatment of thirty-five cases of chorea. Three grains were given three times daily; in a few cases the dose was given five times daily; in one case a grain and a half were given daily. The patients ranged from three to eighteen years of age. The cases presented all degrees of severity. The results were, on the whole, satisfactory; recovery was speedy in mild cases, retarded in severe cases. The duration of treatment was from a week to eight months. The results were the better the earlier in the disease the cases were seen. Unpleasant symptoms, such as tinnitus aurium, a sense of intoxication, disturbances of vision, vertigo, nausea, vomiting, jaundice, increased pain, headache, and cyanosis, were observed in some cases in which the largest doses were employed; but these manifestations ceased upon the withdrawal of the remedy. It seemed as though a certain degree of tolerance of the remedy developed.

For Odontalgia due to Acute Pulpitis.—When toothache is dependent upon acute inflammation of the dental pulp, the distressing symptoms to which the condition gives rise may be relieved by introducing a bit of cotton impregnated with one of the following solutions into the cavity of the carious tooth or teeth, after thorough cleansing:

℞.—Menthol . . . . . gr. xxxvj.
Chloroform . . . . . f℥j.—M.

℞.—Cocaine hydrochlorate } āā gr. iv.
Morphine hydrochlorate }
Creasote, sufficient to make a paste of creamy consistence.

℞.—Morphine sulphate . . . gr. iij.
Atropine sulphate . . . gr. jss.
Distilled water . . . f℥j.—M.

L'Abeille Méd. [*La Sem. Méd.*]

For Hoarseness.—In addition to the measures employed in the treatment of the causative condition, the following formula will prove useful in the amelioration ot hoarseness:

℞.—Acid. tannic. . . . ℥j.
Pulv. sodii biborat. . . ℥j.
Tinct. capsici . . . f℥ss.
Aquæ rosæ . . . . f℥x.—M.

S.—To be used frequently as a gargle. WHITLA.

For Metrorrhagia.—Hydrastinin hydrochlorate in doses of a third of a grain, every six or eight hours, is recommended as a useful remedy in the treatment of metrorrhagia dependent upon congestion or catarrhal inflammation of the uterus. The good results should be perceptible in the course of two or three days.—*Berlin. klin. Wochenschr.*, No. 7.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

THE THERAPEUTIC EMPLOYMENT OF ANTITOXINES.

IN the *Münchener medicinische Wochenschrift* of February 2, 1892, pages 76 to 78, BUCHNER gives a review of the efforts that have been made to apply therapeutically in the management of disease in human beings the results of recent studies upon the *modus operandi* of immunity.

The work of FODAR, NUTTALL, NISSEN, LUBARSCH, BUCHNER, and others, has demonstrated that the blood-serum of certain animals possesses an antagonism to the life of particular pathogenic micro-organisms and that the property is due to the presence, in the serum, of a body belonging to the group of albumins. With this observation as a basis, experiments were made upon the serum of animals under varying conditions, to determine if there existed naturally or could be produced artificially differences in the degree of this anti-bacterial property that the serum was found to possess.

The results of these studies indicate that decided differences in germicidal powers exist between serum from different animals, in its activity against different organisms, and that this property is not confined to an influence upon the living organisms themselves, but in particular cases there is present in the blood of animals a body that is *antidotal to the poisons produced by the bacteria*, without being in any way detrimental to the life of the organisms that produced the poisons.

Most prominent among the results of these studies were the results obtained by BEHRING and KITASATO in their work upon tetanus, which went to show that in certain animals that were susceptible to this disease it was possible to produce a condition of immunity against the inroads of the organism that causes it, and that when immunity was once established the blood-serum of the immunified animal possessed the property not only of affording immunity to other susceptible animals, but had more or less of curative effect when the disease was already in progress. The same authors demonstrated that the blood and serum not only of animals that had been rendered immune to tetanus, but likewise to diphtheria, possessed the power of rendering inert the living organisms that play the etiologic rôle in the production of these maladies. The practical application of this observation to the therapeutics of tetanus was first made by TIZZONI and CENTANNI, who isolated from the serum of immunified animals the anti-tetanus principle, and TIZZONI claims to have employed it with successful results in the treatment of tetanus in the human being. SCHWARZ, assistant in the surgical clinic at Padua, also recently reports (*Centralblatt f. Bakt. u. Parasitenkunde*, Bd. x, No. 24) the cure of a case of traumatic tetanus in the human being by the use of the tetanus antitoxine of TIZZONI and CENTANNI. The case reported by SCHWARZ was one of tetanus resulting from a wound that had become infected through the soil. The tetanic spasms were not affected by chloral, hot baths, or injections of carbolic acid. After three subcutaneous injections of the antitoxine, each injection consisting of from 0.15 to 0.20 grams of the dried substance dissolved in water, the general condition rapidly improved. With continuation of these injections, in slightly increasing doses, the improvement was more marked. After each injection there was a marked fall in temperature, followed by profuse sweating. Toward the end of the injections the primary wound was excised, but this could in no marked way have affected the treatment of the case by the antitoxine, for, as the symptoms showed, there had already been a sufficient absorption into the system of the poisonous products of the organism growing at the point of infection to give rise to the characteristic spasms of tetanus. The case was dismissed from the hospital cured in six weeks.

Another case of cure by this method of treatment is also reported by SCHWARZ as having occurred in Toscana under the management of DR. PACINI.

Still another cure is reported by FINOTTI from the surgical clinic of PROFESSOR NICOLADONI in Innsbruck. This cure occurred in a boy whose hand had been crushed in a machine to such an extent that amputation became necessary. On the eighth day after amputation tetanic spasms began to appear. On the eleventh day the injections were begun, and after twenty-eight injections the case was completely cured.

In a similar line the experiments of KLEMPERER and KLEMPERER in connection with acute fibrinous pneumonia must be looked upon as a bacteriologic triumph, even though they are as yet by no means completed. These observers succeeded not only in rendering susceptible animals immune to the form of septicemia produced by the organism that is believed to be the cause of acute fibrinous pneumonia, but, moreover, demonstrated that the serum of these animals had the power of affording both immunity to the disease, when injected into other animals, and also of bringing about a cure when injected into animals in which the disease is already in progress.

After obtaining these results in the lower animals they directed their attention to the cure of the disease by this means in human beings, and found that by the subcutaneous injection of the serum of immunified animals to patients suffering from acute fibrinous pneumonia the results were in the main promising. They demonstrated that while healthy individuals and those suffering from other forms of disease presented no systemic reaction after the injection of the serum, in six cases of acute pneumonia in which the serum was employed there was a marked fall of temperature and slowing of the pulse within the first twelve hours after it was injected. In four of these cases the temperature fell to normal, but rose again after six hours; in the remaining two it fell to normal and remained there.

At about the same time EMMERICH and FARWITZKY and FOÀ and CARBONE published results of similar nature, in so far as the lower animals were concerned, but obtained by somewhat different means.

Space will not permit of a complete detailed review of all the observations upon this interesting subject, but those that have been cited will suffice to indicate the turn this work is taking and the direction in which it will ultimately find its greatest and most valuable application. The results of purely scientific medical research accumulate more or less slowly, and frequently are of such a nature that they cannot be appropriated by the "busy practitioner," or, indeed, appreciated by him, but when such ends are gained as those just referred to it is difficult to understand the lack of interest and sympathy that so frequently is seen between the practising physician and the laboratory student of medical research.

IRREGULAR MANIFESTATIONS OF MALARIA.

FROM early times, clinical observers have been familiar with the fact that the malarial intoxication is manifested not only in the form of paroxysms of chills and fever, but also under that of various disturbances of the circulation, respiration, and digestion, possibly of nervous origin, and in motor and sensory disturbances of undoubtedly nervous character. An accurate knowledge of the subject, however, has by no means been widely diffused among the ranks of the profession, and prior to the discovery by LAVERAN and other observers of the characteristic hematozoa of malaria, the diagnosis of these cases has invariably been involved in more or less doubt and no little dispute. That "malaria is a cloak for ignorance" has long been a reproach made by the laity against physicians, and the statement undoubtedly contains an element of truth.

From many standpoints the lecture delivered by PROFESSOR DA COSTA at the Pennsylvania Hospital, and reported in the *International Clinics* for October, 1891, is an important contribution to the subject of malarial paralysis. The diagnosis of the case there recorded was rendered absolutely indisputable, not only by reason of careful observation of the symptoms, and by the therapeutic test, but also by the discovery of characteristic parasites in the blood. PROFESSOR DA COSTA lays great stress upon two facts of importance in diagnosis, namely, that there may be an intermittent paralysis which is not malarial, and secondly, that the manifestations of malarial paralysis are in the majority of cases far from being periodic. He distinguishes three forms: First, general paralysis or paraplegia, with irregular symptoms; secondly, the form in which periodicity is striking, which is more commonly hemiplegia; thirdly, the rarest form, that in which organic disease is produced by the malarial intoxication, and in which periodicity and variability are not prominent, the case running much the course of ordinary paralysis when produced by its usual causes. The

last-mentioned form, commonly due to a lesion such as meningitis or hemorrhage, shows itself most often in the shape of a hemiplegia. It is not, strictly speaking, a malarial palsy, although malarial fever has brought it about. It is rather palsy in malarial disease.

In the treatment of malarial palsies quinine must be given in large doses, for "the malady will go on unchecked by small doses—nay, it may develop while these, or even while what are generally considered as sufficient doses, are being employed."

In addition to the palsy of the extremities in the case reported by Da Costa, interesting ocular lesions were found, the details of which have been published in full, with charts, by Dr. Harlan, in the *Transactions of the American Ophthalmological Society*, vol. v, 1890. Headaches, impairment of memory, outbreaks of hallucinations and of maniacal delirium, characterized the progress of the disease. Notwithstanding all this, however, recovery was complete. "Eye symptoms, brain symptoms, all disorder seemed to melt away under the potency" of quinine, coincidently with the disappearance of the microörganisms from the blood.

Less striking but more common than cases of the nature of that described by Professor Da Costa, are malarial neuralgias, especially supra-orbital and infra-orbital. In these cases the manifestations are sometimes, but not invariably, periodic; and the pain, obstinately resistant to ordinary anodyne and nervine medication, rapidly disappears under the influence of quinine; but, as in the cases of palsy, the drug must be given in large doses: ten grains on going to bed, and from ten to fifteen grains upon rising in the morning, repeated for two or three days, have absolutely and permanently cured cases that have resisted not only ordinary treatment, but even long courses of what the elder Gross used to call "piddling doses" of quinine.

THE IMMORALITY OF THE READING-NOTICE.

1. If true to his calling the physician is so far as possible a scientific man—that is, his statements as to disease and the cure of disease are true, and represent the facts.

2. When a physician makes a scientific statement over his own written signature, asserting a fact to be true, it follows that he must have proved the truth of his statement by his own scientific tests, knowledge, and experience, or that he at least has confidence in some person of scientific authority and of undoubted trustworthiness, who has testified to the truth of the statement.

3. The editor of a medical journal is a physician.

4. A statement about medical science in his editorial columns is a personal assurance over his signature on the part of the editor that he knows and guarantees the assertion true.

5. When an editor lends his editorial columns at high prices, and inserts advertisements under the guise of editorial authority, he thereby personally guarantees the truth of the advertiser's statements, or, for a definite bribe in hard cash, he enters into fraudulent collusion with his advertiser to pretend to do so.

6. The reading and editorial columns of a medical journal are, ostensibly at least, for the benefit of subscribers—medical men—and of medicine. The advertising columns plainly stand for what they are—space frankly sold advertisers with no editorial guarantee as to the truth of statements made. The act of smuggling an advertisement into the reading or editorial columns is deception and fraud. Every subscriber should at once resent the insult to his intelligence and morality by stopping his subscription to a journal that thus deceives him, and wrongs medicine.

A large number of medical journals are guilty of this immorality. Just at present there is synchronously appearing an advertisement in the editorial columns of many American medical journals. It is several pages long, alike word for word in each journal, and so cunningly written as to appear the spontaneous and independent assurance of the editor. To the discerning eye, however, it is a shallow advertisement of a secret proprietary preparation, one whose chemical constitution is not known, and therefore one that is squarely against the code of ethics, medical or human, to prescribe or to recommend. These editors aver that "after careful investigation we submit the following as a compendium of an examination of the pathological and physiological action" of the drug advertised. All through the article the editorial "we" is used to praise the drug in the most unqualified manner for a large number of diseases in which "we" have proved it to act "admirably," etc. The editors testify that the drug is "of the amido-benzole series, in combination, and is much to be preferred to any other of this class of derivatives, etc."

Medical writers have long been abusing the lay

and religious press for selling their space to patent medicine men, and lo! our own house stinks!

COPIES OF ADVERTISEMENTS DESIRED.

IN extenuation of the medical sin of sneak-advertising in lay newspapers on the part of physicians, it is often said that it is all the fault of their assistants, of impolitic friends, clinical subordinates, and especially of the pokey-nosed reporters. But it is a noteworthy fact that the gentlemen thus unwisely befriended and deceitfully interviewed pop up in the daily papers with suspicious regularity and persistency, and that other surgeons and experts are never traduced or reported either with or without authorization. This leads to the suggestion that a collection of reading-notices, etc., of these enterprising physicians from the secular and religious papers, extending over a sufficient space of time, would be of interest to the student of psychology and medical ethics. We therefore beg the readers of THE NEWS to send such to this office. What we particularly desire is the reports of "wonderful" and "delicate" and "unique" surgical operations; professional opinions concerning the prevailing epidemic, or fashionable disease; the *obiter dicta* of Professor Supercil or the learned Doctor Greatlite concerning the state of health or dangerous disease of some billionaire, singer, actor, criminal, or statesman, who for the hour may be posing before the public eye. We will classify and index the excerpts in a systematic way, and may give a statistical review of them at some future time, thus adding one more "insertion," as it were, and of course wholly *gratis*. Possibly, in view of this disinterested offer of ours, those most interested might be prevailed upon to spare our correspondents the trouble, by themselves forwarding their own reports and interviews. Their typewriters could supply duplicates, or the reporters by special request would doubtless furnish advance galley-slips. But on second thought we shall be forced to depend upon our subscribers, because, of course, the doctor who secretly advertises does not read THE NEWS.

SELECTIONS.

IMPORTANCE AND NECESSITY OF NATIONAL HEALTH-SERVICE.

IT has long been my conviction that there should be in this, as in every other nation, a systematically conducted central Public Health system, whether called a department, bureau, board, or otherwise; that it should have a responsible head; that it should have the co-operation, and assistance when required, of all State and municipal boards and authorities; that it should be a distinct and separate branch of the public service, having powers, duties, and privileges entirely its own; that it should be unhampered and undisturbed by political circumstances or changes, with ample funds and facilities for the elucidation and treatment of all the great and perplexing problems pertaining to the prevention of disease.

Whatever may be thought or said regarding the centralization of authority in a political sense, here, it seems to me, its advantages to the people of a nation are too apparent to admit the possibility of question.

National control of public sanitation is "protection" in its highest and most beneficent signification.

My own conception of our present pressing need is as follows:

I would have the National Board of Health, as at present provided, rehabilitated and charged with the duty of supervising, particularly all matters of public health in the *interior*, calling it, perhaps, the "Health Department of the Interior;" I would have the Marine-Hospital Service, as at present constituted, especially clothed with powers relating to *external* quarantine; I would have both these departments retained, acting separately under ordinary circumstances, and jointly in certain contingencies when they arise; I would have in connection with this Health Department of the Interior numerous experiment-stations established, which should be entirely under Government patronage and control, and fully equipped with laboratories—chemical, physical, and bacteriological—each with an efficient corps of well-trained scientists, upon the same general plan by which the agricultural experiment-stations are operated; I would have these scientific observers made Government officers, with salaries sufficient to insure against their personal wants, and pensions when retired, in order that their undivided attention might be given to the work for which they are employed; I would have them constantly commissioned to make original and experimental investigations into the ultimate causes of disease, wherever found, and required to report the results for publication and distribution.

As an auxiliary to this Board, I would have a National Congress of Health, to take the place of the present "Conference of State Boards," which should meet at regular intervals—a representative body composed of delegates from each of the State and Territorial boards.

And when, as in logical sequence these proposed premises suggest, an *International Board of Health* shall be established, the most efficient state of development will be attained, and sanitary science will be a mighty messenger to indicate the approach of a perfected civilization, when the protection of the health and life of every human being will be regarded as the highest and most paternal function of the State.

Let us confidently cherish the hope that we soon shall see the day when the public indifference to this all-important subject will be overcome, and when our public servants will be induced to worship the powerful Mammon less and seek the beneficent shrine of the goddess Hygeia more.

My friends, preventive medicine is the most momentous question of our time.

The late lamented Samuel David Gross, the illustrious sage, the prince of American surgeons, at the dedication of the monument erected to the memory of the pioneer of abdominal surgery, Ephraim McDowell, gave utterance to the following significant words:

"Young men of America! Listen to the voice of one who has grown old in his profession, and who will probably never address you again, as he utters a parting word of advice. The great question of the day is not this operation or that, not ovariotomy or lithotomy or hip-joint amputation, which have reflected so much glory upon American medicine, but *preventive medicine*, the hygiene of our persons, our dwellings, our streets—in a word, our surroundings, whatever and wherever they may be, whether in the city, town, hamlet, or country; and the establishment of efficient town and State boards of health, through whose agency we shall be more able to prevent the origin and fatal effects of what are known as the zymotic, or preventable diseases, which carry so much woe and sorrow into our families, and often sweep like hurricanes over the earth, destroying millions of human lives in an incredibly short time.

"The day has arrived when the people must be aroused to a deeper and more earnest sense of the people's welfare, and suitable measures adopted for the protection, as well as for the better development of their physical, moral, and intellectual powers.

"This is the great problem of the day—the question which you, as representatives of the rising generation of physicians, should urge, in season and out of season, upon the attention of your fellow-citizens—the question which, above and beyond all others, should engage your most serious thoughts and elicit your most earnest co-operation.

"When this great object shall be attained, when man shall be able to prevent disease, and to reach, with little or no suffering, his threescore years and ten, so graphically described by the Psalmist, then and not till then will the world be a paradise."—A. Walter Suiter, M.D., *in The Sanitarian, March*, 1892.

CORRECTION OF DISPENSARY ABUSES.

If a free dispensary is so managed as to treat the very poor only, it will do the profession no injury; on the contrary, it will be a positive benefit by relieving the profession of the care of the class that taxes the time and strength of the practitioner without yielding him any return.

Evidently the sticking-point is, who are and who are not proper objects for free treatment? It should be as much the business of a well-conducted dispensary to diagnosticate poverty as to diagnosticate disease, and always the first before the second. How is this to be done?

The ordinary way is by careful questioning, at the same time using the judgment that comes with a large acquaintance with the class in question, to determine how far their statements are to be believed. I usually ask: Are you able to pay a physician? What wages do you or does the head of the house receive? Are you out of work? How many children are in the family? An ideal way is to employ in every case the efforts of a specially organized body whose business it is to find out just what we want to know, and abide by its decision, rendering aid without it only in urgent cases and until it can be heard from. I refer to the Charity Organization Society, which sends a speedy and wonderfully accurate estimate of the ability of the family to pay, and whether or not it should be treated free of charge.

A good way would be to have a central bureau of medical relief, to which the applicant should first go, and which should treat urgent cases without delay, referring them to the general dispensary nearest their homes for further treatment. All others should be carefully examined as to their ability to pay physicians in their own neighborhood. With the recommendation of this central office the patient might be treated at any dispensary for thirty days, when another permit could be issued, and so on.

To go to the central office twelve times a year for a recommendation is surely an easy way to receive medical treatment, if such treatment is necessary. If, however, the patient is able to pay even a small fee to a physician, the dispensary and public opinion, instead of preventing him by any device, should compel him to make such payment as the most honorable of obligations. To give a man what he can by honest labor pay for, is to take the first and a long step toward making that man a blatant communist or beggar, who wants every man with more than himself to divide with "his laziness and improvidence."

While most of the ills that dispensary patients complain of are due to minor ailments preventable or curable by a little care, fresh air, and properly prepared and eaten food, there still remains a goodly number of organic diseases, readily overlooked in the hasty way dispensary patients are often examined. Many are the cases of cardiac valvular disease treated for malaria, while there are doubtless scores of patients upon every dispensary record with undoubted renal disease who are treated for the accompanying dyspepsia, bronchitis, or diarrhea, but where no microscopic examination of the urine has been made.

Unless the dispensary physician is ever on his guard, he tends to become brusque and arbitrary in his dealings with his patients, and hasty and superficial in his methods. I am inclined to believe that no one should hold a position of this kind too long.

An attempt to obtain medical advice by false pretences of poverty should be treated as any other attempt to obtain value without rendering an equivalent. My own practice at present is, as nearly as possible, the following:

Inhabitants of certain squalid alleys well known to me are treated without question, their names, ages, and residences being recorded in a register. The destitute and forlorn, whose aspect is unmistakable to anyone having dealings with the poor, come in first of all for treatment. Mechanics, artisans, or laborers, out of work and out of money, the poor families of drunken and worthless men, are in my opinion entitled to free treatment.

Adults who have to pay for their board and lodging out of their wages when the latter are less than $5 per week, I usually treat free at the Garrett Dispensary.

House servants, earning $10 to $12 per month, can and do pay physicians for advice. I dwell on the pecuniary aspect of the case, since this is where the greatest care should be taken to prevent the pauperization of the patient, and to protect the practising physician.

When in doubt whether the patient, after all, is a fit subject for a dispensary, I have in very numerous instances referred the case to the Charity Organization Society, with most gratifying results. The writer would suggest that a conference of representatives of various dispensaries of Baltimore be held, to which a number of general practitioners living in their immediate neighborhood be invited, at which the entire matter might be thoroughly discussed, and a basis arranged upon which patients will be treated or refused treatment. Such an agreement should be signed by the dispensary physicians and be binding equally upon all. It then should be posted in a conspicuous place in each dispensary. Certainly it is time that something was done in our different cities to check what is already an injury to the public at large, and to the profession in general.—WALTER B. PLATT, M.D., *in Maryland Medical Journal, February* 20, 1892.

DEFECTS IN THE STRUCTURE OR FUNCTIONS OF THE EYES AS A SOURCE OF MORBID PHENOMENA.

A SHORT time ago the editor of THE MEDICAL NEWS directed attention to the fact that a great discovery respecting the relief of human suffering had been ignored by the profession. He showed that as a fact defects in the structure or functions of the eyes actually do cause many morbid states, as headache, vertigo, dyspepsia, constipation, neurasthenia, insomnia, and other ills of kindred nature. He gave some reasons why this discovery had been so commonly ignored by the profession. His neighbor, the editor of the *Medical Record*, an accomplished general surgeon, takes up the matter, and suggests that there is such uncertainty as to what the "great discovery" is that the profession is excusable for ignoring it. He also says that many cases of headache, vertigo, constipation, insomnia, etc., get well without glasses, by the operation of natural causes, by suggestion, or by medicines. We think that these remarks by the *Record* abundantly demonstrate the force of the claim by THE NEWS. From the latter it is very evident that the editor of the *Record* does not himself comprehend the discovery. He also shows that he has not studied with discrimination the writings of ophthalmologists relating to this subject.

In general, it may be said that ophthalmologists do not claim to be able to cure every case of headache, insomnia, neurasthenia, etc., by the use of glasses, prisms, or operations upon the ocular muscles. As a rule these gentlemen are good practitioners of general medicine. Hence, they know that the great proportion of patients suffering from these disabilities are under the influence of other and adequate disturbing causes. They know that the removal of these causes will induce the desired relief. Some may not get enough sleep, some may drink too much coffee, some may suffer from overeating, or eating indigestible food, some may be poisoned by bad air, some from too much worry, etc. But the cases to which THE NEWS refers, and which ophthalmologists have in mind, are the complement of this large class. They are those upon whom hygiene and doctors, homeopathic, eclectic, regular, and defective have exhausted all their resources, and still the disability remains. It may be that the rhinologist has burned out the nose, the laryngologist has scraped and sprayed the larynx, the gynecologist has rendered perfect the organs of reproduction—in short every means and measure has been utilized by the most skilled, and still the patient suffers from headache, has insomnia, is neurasthenic, is constipated, is dyspeptic, etc. In such a class of cases the ophthalmologist has found by experience that his art is able to restore many, if not all, to a normal healthful condition of living. It is this fact that the general profession does not practically know, or, if it does know, it ignores it. The real difficulty in the matter is the intricacy of the problems involved, and the fact that the majority of the profession are not trained so as to be able to comprehend these problems. Hence they permit patients whom they have been unable to relieve to continue to suffer, in the calm belief that medical science can give no relief. We submit that a fair intelligent mastery of the current ophthalmological literature will convince any person that no intricate case of derangement of the nervous or nutritive system is hopeless while the eyes have not been submitted to a thorough examination by one properly trained to do this work. The charge made by THE NEWS was that such cases were daily cast off as hopeless by the general profession without having recourse to a searching examination of the eyes.

Concerning this sort of examination, any physician can become skilled in making it. But its draft upon a peculiar kind of knowledge and skill is so large that we suspect that most will not care to qualify themselves. Hence it will be imperative that they refer the class of patients under consideration to other physicians whom they know to be competent for this work. The main point is the assurance that suffering human beings secure all the relief that modern medical science, including ophthalmology, can give. Certainly it is no light matter to ignore the claim of ophthalmology to be able to relieve vast numbers of the suffering that no other means has been able to relieve.—*Editorial in the American Lancet, March*, 1892.

CORRESPONDENCE.

URIC ACID AND RHEUMATISM.

To the Editor of THE MEDICAL NEWS,

SIR: In the issue of THE MEDICAL NEWS of February 13, 1892, Dr. W. E. Shotwell propounds the question, "Is uric acid a prime or sole factor in the causation of rheumatism?"

One of the most important factors to be studied in relation to this subject is diet. On this subject the author of the article referred to seems to be greatly at variance not only with competent authorities, but also with well-established chemico-physiologic laws. Uric acid is not "produced in the system by a stimulating nitrogenous diet and the use of alcoholic beverages." A nitrogenous diet is not stimulating, and the proof of

this statement is most readily determined by the nature of its chemical formation and by the results, necessary time, and mode of conversion into the final products of oxidation.

As to the use of alcoholic beverages, it might be said that alcohol in quantities that exceed the accommodative capacity of the system are damaging to the organism to the extent of their use of oxygen. The physiologic extent of accommodation differs greatly in individuals. There is practically no difference in the nature of the members of the carbohydrates and alcohols. All of them—starch and sugar—have to be converted into a glucose or alcohol-like compound, or an isomer of one or the other, before they can enter the system. The members of this group never enter the system, therefore, under their own form, and if alcohol is to be abolished from the rheumatic dietary, so should the sugars or those compounds that are converted into glucose or its isomer. Properly speaking, uric acid is not produced by anything, but it is the result of a suboxidation of the proteid food-stuffs. This incomplete transformation of the proteids follows the ingestion of a larger amount of the CHO compounds than the organism can appropriate and utilize as heat, energy, lubrication, and rotundity of form. It is a well-known fact that a CHO molecule is more easily oxidized than one of proteid nature, and being more easily changed into its final products—carbon dioxide and water—uses all the oxygen it desires, leaving but an insufficient amount for the proteids. We must remember that the oxygenating capacity of the system is a limited one. The consequence of this is that we have circulating throughout the body such products of incomplete tissue-metamorphosis as uric acid, kreatinin, kreatininic leucomaïnes,[1] glucose, lactic acid, oxalic acid, hippuric acid, etc., as we know them, or antecedents to these compounds.[2]

We consider, therefore, that uric acid in the urine is but the expression of deranged metabolism or incomplete oxidation of the proteid elements.

The reasoning according to which "uric acid, by its irritating influence upon the low-grade tissues of the body, gives rise to rheumatic attacks," we are obliged to consider as without any clinical, chemical, physiologic, or pathologic proof, and in direct variance with well-established and chemico-physiologic facts. Clinical observations must not be regarded as infallible. They are of value only when the laws governing the animal organism are given due consideration, and the interpretation of cardinal signs is in accordance with the results of post-mortem experience. It is admitted by all, and most scientifically explained,[3] that the presence of uric acid in the various structures of the body gives rise to certain manifestations that we term gout. There seems to be no doubt but that rheumatism is caused by a special poison of a non-bacterial, *i. e.*, chemical, nature. Porter and other authorities advance the hypothesis that it is directly dependent on the formation and retention within the connective-tissue structures and intermuscular planes of lactic acid, or its antecedent compounds. Abundance of clinical evidence, the study of body-oxidation, and the products of its incomplete performance, seem clearly to demonstrate the possibility, and greatly strengthen the probability of the hypothesis. It is found that lactic acid is a direct product of suboxidation of a proteid molecule. For if we attack the proteid with 139 parts of oxygen we get the normal waste-products, urea, uric acid, kreatinin, carbon dioxide, water, and a molecule of sulphuric acid, as follows:

$$C_{72}H_{112}N_{18}O_{22}S + 139\,(O) = 4\,(CH_4N_2O) + C_5H_4N_4O_3 + 2\,(C_4H_7N_3O) + 55\,(CO_2) + 38\,(H_2O) + H_2SO_4.$$

If, however, the suboxidation is to the extent of where only 94 parts of oxygen are used, we have added lactic acid ($C_3H_5O_3$) as follows:

$$C_{72}H_{112}N_{18}O_{22}S + 94\,(O) = 2\,(CH_4N_2O) + 2\,(C_5H_4N_4O_3) + 2\,(C_4H_4N_3O) + 7\,(C_3H_6O_3) + 31\,(CO_2) + 19\,(H_2O) + H_2SO_4.$$

Another fact that should be considered is that when a muscle contracts vigorously it becomes acid. This acid in a certain per cent. is a natural product of energy, which is the result of oxidation, or in other words, a certain per cent. of this acid present in the tissue is directly due to normal oxidation.

Numerous researches by competent observers (Berzelius, DuBois-Reymond, Kuhne, Heinheim), have shown that this acid is lactic acid. When the metabolic processes are at fault from dietetic or other causes, this result of katabolism is not disposed of in the usual way, but is left to act as a local irritant.

Although the positive proof of the nature of the poison beyond that given is lacking, we at the same time possess the negative information that it is not uric acid, and "so rheumatism and rheumatoid arthritis are easily distinguishable from gout, where undoubtedly sodium urate is the poison." (Garrod.)

There is a difference between the two conditions—rheumatism and gout—etiologically, symptomatologically, and pathologically. The two are distinct. When we place both these conditions under the influence of a proper diet they disappear. The non-appearance and decrease of these products in the urine under treatment that insures thorough oxidation of the proteid compounds is of the greatest weight in favor of the foregoing statement. It is common clinical experience to see gout and rheumatism both present in the same individual at the same time. How can the presence of two such dissimilar diseases be explained by the novel method of reasoning that they are both caused by the same poison?

If humanity should receive the education desired by the author of the article under consideration, apoplexy, Bright's disease, tuberculosis, diabetes, and all the diseases of which the great etiologic factor is decreased nutrition and vitality would be greatly increased, and man be in a most miserable condition.

Very respectfully, JAMES WOOD, M.D.

"INFECTION AND CONTAGION."

To the Editor of THE MEDICAL NEWS,

SIR: I have read with much interest your editorial in THE MEDICAL NEWS of February 20th relative to the words *Infection* and *Contagion*. In any discussion, an

exact agreement as to the meaning of the te rms used is of the highest importance. There is no doubt that a great deal of inexact thinking, false reasoning, and many erroneous conclusions, in medicine as in other sciences, result from a lack of clear definitions.

The dictionaries often help on the confusion. No one can tell from Webster or Dunglison, the exact difference between contagion and infection, any more than he can between the words hallucination, delusion, and illusion. How, then, shall it be settled? By mutual agreement? There are too many to agree. A proper definition of a term is not one which someone thinks that it ought to have, but that which it actually does have. How shall that be determined? In two ways—first by its etymology, and second by its use.

If we thus examine the two words in question, and find the fundamental conceptions which underlie them, we shall find that a correct conclusion may be reached. It appears to me that, from its etymology, the meaning of each of those words is reasonably clear and definite, and that when one carefully observes the sense in which they are used by the majority of educated medical men, it will be seen that they are more often used in their proper and etymologic sense than otherwise.

What is wanted is clear definitions, clearly stated, and the reasons for them. A lexicographer or a grammarian arrives at a standard definition, or a standard form, by a study of its derivation and its actual use. This, when formulated, furnishes a rule for the guidance of the uninformed, and in doubtful cases. Let us examine these words and find, if we can, their underlying, basic meaning.

Infection is from *inficio*, from *in* and *facere*, to do to—to do [something] to [somebody or something]. Infection is something done *to* some one or something, *specified: by* someone or something, *not specified*. Thus Webster's primary definitions of infect are, to stain, to taint, to affect with anything. The underlying idea is an impression upon something, by something else, foreign to itself—that is all. This is precisely the sense in which it is used in medicine. Although it is often used carelessly and loosely, and without a distinct and definite idea of its meaning, yet more often it is used with the meaning stated.

An infectious disease is a diseased condition or action of an organism, produced by some morbific entity foreign to itself. The morbific entity, from wherever coming, is an infection. It matters not whence it comes, whether from earth or air, or from some other similarly diseased organism. This definition excludes heat and cold, and generally all diseases that are autogenetic. Malarial fever, cholera, typhoid fever, and smallpox are infectious. The morbific agent comes from without; from the "not me."

Contagion, from *con* and *tangere*, conveys the idea of touching, of contact. Something [definite] is touched, or affected, by something else [also definite]. It is not necessary that the contact be immediate. It may be mediate contact. A may strike B with his fist; that is immediate contact. He may throw a stone and hit him; that is mediate contact.

Contact, or contagion, supposes two definite things; one transmitting something to the other, or affecting the other. That is just the sense in which it is used in medicine.

A contagious disease is one produced by some entity foreign to itself [*i. e.*, infection] *and* which infection emanates from some other organism affected with the same diseases, by the contact, mediate or immediate, whether there be actual contact, as in scabies, whether contact through the air, as in smallpox, or by fomites. These are the etymologic meanings, and the meanings most often used, though perhaps not clearly formulated by all who so use the words. Infection is a more comprehensive term than contagion. It includes it and much more. All contagious diseases are infectious, but not all infectious diseases are contagious. Some A is all B.

What of those infectious diseases [produced by a foreign morbific material] and which are not contagious [the morbific material not coming from another case]? They are miasmatic diseases, of which malarial fever is a type. Paludal miasm is an infection, but not a contagion.

It is quite true that the greater number of infectious diseases are also contagious, yet the distinction is broad and clear, and should be kept so in our minds and in our speech. Our facts may be errors, our theories may be false, yet that is no reason why they should not be clearly stated. If those who know the right will persistently follow it, the unthinking, the undecided, and the mistaken will of necessity, sooner or later, fall in with them. It is an interesting fact, that in those infectious diseases which are contagious the morbific material undergoes unlimited development and multiplication [zymosis] in the person of the individual affected, and the dosage is a matter of comparative indifference.

A microscopic particle of smallpox virus will produce, in the subject infected with it, enough to infect all mankind. This is not true of those infectious diseases which are not contagious, but are miasmatic. The morbific material is not thus multiplied in the subject infected, and the effect produced by the infection is in direct proportion to its quantity.

Let us, then, construct a formula as follows:

INFECTIOUS DISEASES.	*Contagious Diseases.*	The morbific material comes from another individual with the same disease.	The morbific material is indefinitely multiplied in the infected individual. Dosage immaterial.
Those produced by a morbific material from without.	*Miasmatic Diseases.*	The morbific material does not come from another case of the same disease, but from any source.	The morbific material is produced independently of any living being, well or ill. The effect produced is in direct proportion to the dose.

Very respectfully,

J. E. TEFFT.

SPRINGFIELD, MISSOURI.

VOMITING AFTER OPERATIONS.

To the Editor of THE MEDICAL NEWS,

SIR: In the March number of the *American Journal of the Medical Sciences*, my friend, Dr. John B. Roberts, writes as follows:

"For the nausea and vomiting which occur after inhalation of ether, I usually do nothing except to have the patient's head so placed that any ejected material may easily escape from the mouth. Little actual vom-

iting occurs if the patient has been given the preliminary hypodermatic injection, and especially so if he has taken no food for several hours before the operation. The practice of giving drugs to combat vomiting is, I believe, unnecessary and unreasonable, unless the vomiting shall be prolonged and evidently depressing to the patient. Draughts of hot water for the relief of ether-vomiting are given by some physicians, and in some cases may be desirable, as retching, when the stomach is empty, is often more disagreeable than vomiting water which has been put into the stomach."

My own experience, which is confined to a limited class of cases, and does not include general surgery, has impressed me with the fact that vomiting after operations is often quite frequent, always annoying, and, at times, of such severity as to be alarming, and even threaten a serious disturbance of the dressing, if not detachment of the sutures, with its evil consequences. I have often seen severe vomiting or retching follow the use of ether-chloroform, with and without the previous hypodermatic of morphine, alone or combined with atropine, and in cases in which no food had been administered for hours previously to the operation. This happened to me recently in a patient who had been most carefully "prepared," and also had taken ether for an operation on the perineum. At the present writing a patient is only just sleeping quietly after thirty-six hours of retching and vomiting following chloroform-narcosis for the removal of a large fibroid attached to the fundus uteri. In neither of these cases was there the slightest sign of sepsis.

Both of these cases were at once relieved by hourly doses of one drop of tinctura iodi and one grain of carbolic acid in a half-ounce of cinnamon or aniseed water.

The last-mentioned case at first vomited bile, and then the retching was most distressing. She drank water as hot as she could tolerate it—at her own request—which at first gave relief, but was then vomited *en masse*. Ice could not be borne; fomentations had no effect; cocaine was tried with temporary relief; small doses of morphine and atropine increased the trouble, and finally the mixture indicated had a quieting effect.

I have used cerium oxalate, strong coffee, drop doses of wine of ipecac (repeated every ten or fifteen minutes), iced champagne, brandy and crushed ice, mustard or cantharides to the epigastrium, sips of hot water, aromatic spirits of ammonia, peptonized milk, malted milk, frozen beef-tea, chloroform water, with at times good results, but I must say the iodine and carbolic acid (not original with me) have served me best of all. Respectfully yours, J. M. KEATING.

COLORADO SPRINGS.

THE IRREPRESSIBLE QUACK.

To the Editor of THE MEDICAL NEWS,

SIR: In THE NEWS of February 13th there is an article on the "Salutary Effect of State Medical Examining Boards," stating that the Examining Board of Washington had rejected one-half of the applicants. This is true, and our Board is doing good work, and we have a good law if it were enforced—but there's the rub. It will soon be two years since our law went into force, and there have been no convictions for illegal practice. The member of the State Examining Board here is a homeopath, and we thought from the manner in which he started in to prosecute illegal practitioners in Spokane that we would have the law enforced. He began with Dr. Carey, the head of the "Biochemics." Carey was convicted in the two lower courts, and has carried his case to the Supreme Court. The expenses of prosecution have been paid by the regular Medical Society of Spokane. There has as yet been no final decision in the Carey case.

The next case was that of one Reddy, a man that had a 10-cent barber shop in Seattle three years ago. He advertises and does not pretend to have attended any medical school. In the first trial the jury disagreed, and another day is set for a new trial. Reddy then had Dr. Penfield's father arrested. Penfield is a member of the Board of Examiners, and was carrying on the prosecution here. The law provides that all physicians coming into the State after the law took effect should pass an examination. At the trial it was proved that Dr. Penfield, Sr., had sent his diploma to his son here to have it registered under the old law months before moving to Spokane. Again, the jury disagreed. At the next trial of Reddy there were no witnesses present, and the case was dismissed. Since then there have been no arrests. There are at least fifteen persons practising illegally in Spokane. They make no pretence of complying with the law. I will send you a copy of the *Northwestern Journal of Biochemistry*, one of the greatest medical monstrosities of the day. These men composing the faculty were not physicians, but they procured a charter, which was granted on the 19th of June, 1889. On the 29th of June, 1889, they issued a number of diplomas. They registered their diplomas under the old law, and on that registration they claim a right to practise.

The article in THE NEWS of February 13th would lead people to believe that Washington was no place for quacks, but they live and thrive here.

Respectfully yours, W. R. FREEMAN, M.D.

SPOKANE, WASHINGTON.

CHICAGO.

Decline in Death-rate from Typhoid — Women Physicians and Trained Nurses at the World's Fair — Charges against City Health Commissioner — Reporting and Placarding Cases of Typhoid.

TWENTY-EIGHT deaths from typhoid fever were reported in this city the last week in February, a decrease of nearly one hundred per cent. from the preceding week, when the record of fifty-two deaths was itself a marked decrease from the week preceding. Health Commissioner Ware is confident that the month of March will show a continued diminution in the number of deaths.

March 7th, the women physicians and trained nurses assembled in response to a call to hear reports and adopt plans in the interest of the profession for a display at the World's Fair. The call was signed by Dr. Frances Dickinson as Chairman, and by Drs. Isabella Hotchkiss, Marie Reasner, Katherine Miller, and Isadore L. Green. The meeting is the fourth that has been held. At the first one, on October 23, 1891, an address was delivered by

Dr. Frances Phillips, President of the Illinois Woman's Exposition Board, who invited the profession, and particularly the trained nurses, to make a special display at the Columbian Exposition, which should include an emergency ward. The suggestion was eagerly accepted, and a committee was appointed with instructions to invite the coöperation of the trained nurses of Illinois, in order that the emergency ward should represent the women physicians, surgeons, and trained nurses of the entire State. On February 25th, the Illinois Woman's Exposition Board put its seal on the project by appropriating $6000 of its $80,000 State fund for the proposed display. It was largely for the consideration of the best disposition of this money, and to discuss the means of securing the best results with it, that the meeting was held.

The interest in the project was abundantly shown at the meetings. The proposed exhibit was discussed by several speakers, among whom was Dr. Dickinson, who said that the display of the medical women and trained nurses of Illinois should, and probably would, form one of the most striking features of the women's exhibit at the World's Fair. The spirit of emulation was aroused by the statement that a leading feature of the exhibit to be made by the women of Great Britain would be a complete exposition of the methods of nursing employed in England, and which have attracted attention the world over. The friendly rivalry thus created between the methods employed across the water and those in vogue here would, it was suggested, lead to excellent results in the way of improving the service. A number of prominent women physicians and trained nurses from England would, it was said, visit the Fair, and the Illinois woman's display would naturally come in for a great deal of attention. For this reason, it was declared, the display should be in every way complete and a credit to the profession.

During the examination of applicants for position in the Army Medical Corps, held here in February, it is said that out of twenty-four who took the examination, but two passed.

Charges of professional discourtesy, arbitrary conduct, and officiousness, were preferred against our City Health Commissioner at a recent meeting of the Chicago Medical Society. The charges were embodied in a petition that had been actively circulated among the members of the local medical profession asking for an investigation into the methods employed by the Health Department relative to reporting contagious and infectious diseases.

In the early part of February last, Commissioner Ware sent to all physicians postal cards requesting them to report to the Health-offices all cases of typhoid fever coming under their care, as the report was of vital importance as a matter of record. The card also stated that premises would not be placarded for typhoid fever. A week after he received a letter from a prominent physician to the effect that he would make no such report, unless he received positive assurance of being paid for such services rendered to the Health-office. He was opposed to the ordinances that compel a physician to report contagious cases to the Health-office. He considers the law unfair in this regard. What right has the city to ask a physician to do its work for nothing? In England they do things better. They give a physician a fee for reporting cases of contagious disease. The fact is, said this prominent physician, the methods employed by our health and sanitary departments are wrong. The law that places a placard quarantining a house in which is a contagious case is a relic of barbarism, a practice of medieval times, and it does a great wrong many times. Take the case where the placard is nailed on the door of a man who has a small shop under his living rooms. That man's business is ruined for two months at least. Now, is it fair or right that he should suffer simply because there is some danger that the contagion will spread beyond his house? Nothing can be done toward properly quarantining people until a contagious hospital is built.

REVIEWS.

Diseases of the Skin. A Manual for Practitioners and Students. By W. Allan Jamieson, M.D., Extra Physician for Diseases of the Skin, Edinburgh Royal Infirmary. Third edition, revised and enlarged, with woodcut and nine colored illustrations. Philadelphia: Lea Brothers & Co., 1892.

It has been but a short time since the first edition of this excellent book made its appearance, and the profession and the author alike are to be congratulated upon the present edition, which brings the subject-matter, and especially the new remedies, well up to date. Among diseases that have been elaborated or newly introduced, we may mention dermatitis herpetiformis, pityriasis maculata, lymphangioma circumscriptum, pityriasis rubra pilaris, xanthoma diabeticorum, and leprosy. The classification presented is that of Bulkley, which is a complete and elaborate scheme. The subject-matter throughout the work is handled in an intelligent, plain, practical manner that betokens familiarity with the diseases considered. The symptoms and treatment receive especial attention—pathology being, we think, somewhat slighted. Everywhere we note a sense of discriminating power and an endeavor to separate the grain from the chaff. Originality, personal experience, and reports of cases are noticeable features that give interest to the book. These points serve to distinguish it from some of the older classic works on dermatology that deal with the subject in a more systematic way. The book can hardly be called a complete system of skin-diseases, no effort apparently being made to include the whole field. Considerable space is devoted to certain of the rarer diseases, some of which might with propriety have been given to several of the commoner affections. We must regard the work, therefore, as better adapted to the needs of the practitioner than to those of the student.

A test of the worth of a treatise on diseases of the skin is the manner in which eczema is considered. This chapter in the book before us, while it cannot be regarded as exhaustive, contains much of value and merit. We desire to call attention especially to the chapter on eczema as influenced by age, including infantile eczema; and also to the remarks on eczema of the climacteric period, both of which are suggestive.

The treatment of the disease receives due space, the various new modes of local applications that have latterly been introduced, including gelatin and similar dressings, pastes, and spread plasters and muslins, being referred to. Much practical information will be found in the chapter on this subject, together with instructions as to the proper employment of such recent remedies as chrysarobin, resorcin, ichthyol, and the numerous medicated soaps.

As already intimated, an honest, wholesome spirit pervades the volume, which makes itself felt nowhere more forcibly than in the parts devoted to therapeutics. With some diseases more space might well have been given to therapeutics; thus, that distressing and often rebellious affection pruritus genitalium is dismissed with apparent haste, making us wish that the author had told more that he surely knew.

The scope of the work is more cosmopolitan than is usual with English writers, mention being made here and there of the discoveries and labors of dermatologists of various countries. We note that authors are not infrequently quoted without references—an omission that is to be regretted, for the student is thus deprived of the opportunity of consulting the originals. The chromo-lithographic plates, nearly life-size, which are scattered throughout the pages are variable as to merit, but are better than are usually found interleaved in text-books. They represent some of the rarer affections, such as dermatitis herpetiformis, morphœa, acute lichen planus, lichen verrucosus, and tuberculosis of the skin. The general appearance of the book is highly creditable to the publishers. We wish the work the cordial reception it deserves.

The Treatment of Typhoid Fever, and Reports of Fifty-five Consecutive Cases, with only One Death. By James Barr, M.D., Physician to the Northern Hospital, Liverpool; Medical Officer of Her Majesty's Prison, Kirkdale, etc. Introduction by W. T. Gairdner, M.D., LL.D., Professor of Medicine in the University of Glasgow, etc. 8vo, pp. 212. London: H. K. Lewis, 1892.

There is no specific treatment for enteric fever. It is probable that there never will be, notwithstanding the specificity of the disease. Nor is it reasonable to hope that the disease will ever be entirely stamped out. By careful observance of prophylactic measures the risk of infection can be reduced to a minimum and extension can be limited. The invasion of the disease once established, the futility of any efforts to destroy the infective agent must be realized. It remains to treat symptoms as they arise, and by anticipating possible complications to prevent their occurrence. Any therapeusis that will minimize the risks and dangers of the natural course of the disease will commend itself. That hydriatic measures, rationally applied, will meet the indications has been amply demonstrated, and among these the cold bath has proved itself one of the most useful. The employment of the cold bath in febrile conditions, and especially in enteric fever, is attended with certain minor difficulties. Dr. Barr has sought to overcome these by keeping the patient continuously in the bath. For this purpose he employs a tank, six feet long, nearly three feet wide, and sixteen inches deep, lined with lead and having a capacity of seventy gallons. The patient, wrapped in a blanket, rests upon bed-ticking, the head, of course, not being immersed. Special provision is made for carrying off the dejections and for renewing the water, as well as changing its temperature, as occasion demands. A thermometer is constantly kept in the tank. As long as the temperature of the patient is over 100°, that of the tank need not be more than 93°, but as the body temperature approaches the normal, so should the tank temperature. Dr. Barr reports fifty-five successive cases of enteric fever, with one death. Twenty-two cases were treated in the tank; eleven received some special form of treatment, such as the wet-pack, etc.; twenty-two received symptomatic treatment. Eighteen of the patients were less than fifteen years old; twenty-nine were between fifteen and thirty; five were more than thirty. Albumin was present in the urine at one period or other in twenty-seven cases. Rose-spots were found in thirty-five. Spleen was enlarged in forty. Ankle-clonus was elicited in twenty-six. Intestinal hemorrhage occurred in four. Meningitis developed in two. Respiratory complications appeared in thirty. There were relapses in four.

The Anatomical and Histological Dissection of the Human Ear, in the Normal and Diseased Conditions. By Adam Politzer, M.D., Professor of Otology in the Imperial-Royal University of Vienna. Translated from the German by George Stone, of Liverpool. With 164 illustrations and 1 plate. London: Baillière, Tindall & Cox, 1892.

In this valuable work, so ably translated into English, the reader is first informed as to the necessary instruments, then he is inducted into the method of removal of the organ of hearing from the dead body, for anatomical purposes, without visible injury to the skull; and, thirdly, examinations of the cranial cavity and brain in middle-ear suppuration, and in cases of cerebral disturbances of hearing terminating fatally, are fully considered. Then follow chapters on "Dissection of the Macerated Temporal Bone;" "Anatomical and Pathologico-anatomical Preparation of the Organ of Hearing" (an exhaustive chapter of over one hundred pages); "Making Preparations of the Organ of Hearing by the Process of Corrosion," and "Mounting and Preserving Anatomical and Pathological Preparations of the Ear." Then follows a "Special Part," divided into the following chapters: "Histological Examination of the Auricle and of the Cartilaginous Meatus;" "Histological Examination of the Lining of the Osseous Meatus;" "Histological Examination of the Membrana Tympani;" "Histological Examination of the Mucous Lining of the Tympanic Cavity;" "Histological Examination of the Ossicula;" "Histological Examination of the Intertympanic Muscles;" "Histological Examination of the Eustachian Tube;" "Histological Examination of the Labyrinth;" and "Histological Examination of the Central Course of the Nervus Acusticus." This work is indispensable to the anatomist and scientific aurist.

The first number of *The Practitioner's Monthly*, edited by C. L. Dodge and J. Chambers, with associate editors, and published at Kingston, N. Y., claims that it will be cheap, bright, honest, independent, and devoted to the interests of the country practitioner.

MEDICAL DIAGNOSIS, WITH SPECIAL REFERENCE TO PRACTICAL MEDICINE.[1] By J. M. DA COSTA, M.D., LL.D. Seventh edition. Illustrated. Philadelphia: The J. B. Lippincott Co., 1890.

IT is practically impossible to review the seventh edition of Da Costa's *Diagnosis*, without repeating, to a very great extent, the laudatory opinions that have already been expressed in THE MEDICAL NEWS, as well as in other American medical periodicals.

Of this edition it may well be said that the author has succeeded in placing it abreast of the times. This is an accomplishment in which books that have reached a seventh edition often fail, for, like ships that have been rebuilt several times, they too often prove more unsatisfactory to their owners than would new vessels. The only portion of the book that invites criticism is that upon gastric disorders, in which the subject of testing the stomach contents is not considered. We presume, however, that the eighth edition will contain information in regard to this important advance in medical diagnosis. The book stands to-day, as it has always stood, an honor to American medical authorship; a trusted guide to the practitioner; and a credit to the eminent teacher who produced it. In proof of its usefulness and accuracy, it need only be said that a French translation has just appeared, and that a second edition of the German edition has been called for.

Dr. Da Costa's long experience as a teacher in Jefferson College has fitted him in a peculiarly thorough manner for knowing exactly what the student and physician need, and the result is mirrored more clearly than ever in this, the latest edition of his book.

NEWS ITEMS.

The Medical Colleges of the United States.—The following table has been prepared from the *Report of the Commissioners of Education* for the year 1888–89.

	Number of schools.	Professors and instructors.	Students.	No. of graduates at commencement of 1889.	Amount of State or municipal aid received within a year.	Benefactions.
Regular,	92	1907	12,338	3296	$24,820	$87,139
Eclectic,	9	116	669	186	.....	5,200
Homeopathic,	14	249	1,159	312	25,000	16,004
Physio-medical,	1	11	15	5	.....	200
Post-Graduate,	7	261	909	25	.....	19,600

The Section on Ophthalmology at the Pan-American Medical Congress.—This Section has been organized by the election of Dr. Julian J. Chisolm, of Baltimore, as Executive Chairman, Dr. George M. Gould, of Philadelphia, as English-speaking Secretary, and Dr. J. Harries Pierpont, of Pensacola, Fla., as Spanish-speaking Secretary. The foreign secretaries of this Section so far appointed are: Dr. Barraza, Cordoba 1471, Buenos Ayres, the Argentine Republic; Dr. Hilario de Gonvêa, Rio de Janeiro, Brazil; Dr. G. H. Burnham, Toronto, Canada; Dr. Proto Gomez, Carrera 8, No. 370, Bogotá, U. S. of Colombia; Dr. Juan J. Ortega, Ciudad de Guatemala, Guatemala; Dr. Juan I. Urtecho, Calle Real, Ciudad Granada, Nicaragua; Dr. Enrique López, Obropia 51, Habana, Cuba; Dr. Joaquin de Salterain, Canelones 8, Montevideo, Uruguay.

Resident Physicianship at the Methodist Episcopal Hospital.—An examination for the position of resident physician in the Methodist Episcopal Hospital of Philadelphia will be held on Tuesday, March 29, 1892, at the Hospital, Broad and Wolfe Streets, Philadelphia, at 8 P.M.

The examination is open to both men and women; but applicants must, in accordance with the charter of the hospital, have the degree of bachelor of arts. Two resident physicians will be selected by the Trustees from the candidates who obtain the first four places in the examinations by the Medical Board.

Applications should be made to Dr. John B. Roberts, 1627 Walnut Street. Dr. Richard C. Norris, 1028 Spruce Street; Dr. William C. Hollopeter, 1408 N. Thirteenth Street; Dr. H. H. Kynett, 1728 Spring Garden Street.

International Periodical Congress of Gynecology and Obstetrics.—The Belgian Society of Gynecology and Obstetrics, under the patronage of the Belgian Government, has taken the initiative in organizing "The International Periodical Congress of Gynecology and Obstetrics," the first session of which will be held in Brussels, September 14 to 19 inclusive, 1892. Three leading questions will be offered for discussion:

1st. Pelvic Suppurations. Referee, Dr. Paul Segond, Paris.

2d. Extra-uterine Pregnancy. Referee, Dr. A. Martin, Berlin.

3d. Placenta Previa. Referee, Dr. Berry Hart, Edinburgh.

The fee for members participating in the first session will be thirty francs, which will entitle to a copy of the *Proceedings* of the Congress.

Founders (life membership) pay a fee of three hundred francs.

In connection with the Congress there will be an International Exposition of Instruments and Appliances pertaining to Gynecology and Obstetrics.

All communications pertaining to this Congress should be mailed directly to the American Secretary, Dr. F. Henrotin, at Chicago, Ill., who will promptly furnish all information. All notifications to be forwarded should be received by August 1st.

[1] Owing to an inexcusable inadvertence, this review is published at this late date.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment, provided that the request for reprints be noted by the author at the top of the manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

PRE-ATAXIC TABES DORSALIS, WITH OPTIC-NERVE ATROPHY.

BY HOWELL T. PERSHING, M.Sc., M.D.,

PROFESSOR OF NERVOUS DISEASES IN THE GROSS MEDICAL COLLEGE, DENVER, COLORADO; PHYSICIAN TO THE ARAPAHOE COUNTY HOSPITAL AND TO ST. LUKE'S HOSPITAL.

THE following cases are reported because they belong to a well-defined variety of disease that is worthy of special discussion on account of certain peculiarities, both as to diagnosis and prognosis.

CASE I.—C. L., a printer; is thirty-eight years of age. His mother died of "neuralgia of the stomach." One of the mother's sisters was insane, and the patient's only sister is very nervous and excitable. He has used tobacco and malt liquors in moderation. He had a single venereal sore four years ago and several a year later. An eruption (diagnosticated syphilitic) was present a few months ago. For three years past he has had an annoying tremor during effort or excitement. Vision began to fail in the left eye in April, 1889, and grew steadily worse until January, 1890, when vision in the right eye also became much impaired, the left seeming to improve. Transient ptosis on the left side was noticed several times. The knee-jerks were found absent in November, 1889. Potence was lost soon after failure of vision. The man could read with the right eye up to June, 1890, when atropine was instilled, causing immediate loss of power to read, which did not return. During the summer and fall of 1890, there were shooting pains in the legs and occasional retention or involuntary evacuation of urine.

Present condition, November, 1890: Can barely see a hand close to face. Cannot count fingers. Pupils equal, moderately contracted; light reflex scarcely perceptible; accommodation reflex could not be tested. White atrophy of both optic discs.

Knee-jerks entirely absent, even with Jendrassik's reinforcement. Plantar and cremasteric reflexes present; abdominal excessive. Station with eyes closed normal; stands on either foot. Walks backward perfectly well. No ataxia of arms or legs, unless in left leg in so slight a degree as to be doubtful. No intention-tremor is present, no paralysis, and no wasting. No defect in touch, pain, posture, temperature, or muscular sense is detected by careful examination. Hearing is normal for watch and tuning-fork, and the auditory field is not limited for high notes. Taste and smell are normal. The pharynx and larynx are normal, except that the reflexes are heightened. He complains of shooting pains, especially in the left thigh and testicle, though these are not severe. There is a feeling of tremor in the intestines and genitals; a numbness of the buttocks and rectum; a lack of normal sensation during defecation, and, at times, involuntary defecation. Normal action of the bladder and potence have returned, apparently owing to the administration of strychnine.

On January 31, 1891, he reported that two nights previously his breathing was suddenly stopped by what seemed an obstruction in the throat that could not be cleared by coughing; he was greatly alarmed and trembled violently. (Laryngeal crisis.)

CASE II.—E. P., a shoemaker; is fifty-three years of age, and married. His mother died at seventy-six, of "softening of the brain." Father, brothers, and sisters are said to be very nervous. Two brothers and three sisters died of pulmonary tuberculosis, one brother of diabetes. He has been a constant though moderate chewer and smoker, but has never been a drinker, and there is no syphilitic history, though he admits exposure.

Sudden blurring of vision in the left eye occurred five years ago, which was said at the eye dispensary to be due to an affection of the nerve. Recovery took place in a week. For four years past he has had annoying sensations in the soles, palms, instep, and inside of elbow, making it difficult to keep still. The thighs feel as though abraded in front. Sometimes the touch of the bed-clothes is unendurable. In July, 1890, the left eye again began to fail, and has grown worse. A few months later the right was affected. Of late there has been drooping of the left lid. Difficulty in urination is complained of, there being no force to the stream. Putting the hands in cold water causes involuntary micturition. Potence is much diminished; at times there is absolute impotence. He has had hard coughing spells, without apparent cause and without expectoration.

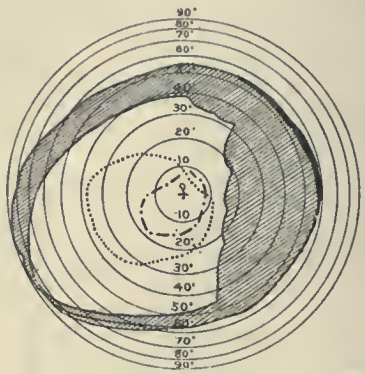
The present condition, January 15, 1891, is as follows: Vision: right, $\frac{5}{6}$; left, $\frac{5}{10}$. The fields are much contracted, both for white and colors, especially on the nasal side. (See the annexed diagram.) Both optic papillæ are sharply defined and of a grayish tint. The right pupil reacts well to light; the left is contracted, irregular in contour, with light reaction barely perceptible. Both react well in convergence. The knee-jerks are present, and are increased by reinforcement, but the left is considerably less than the right, which is rather below the average. With eyes closed he can stand on either foot, and walks well. There is no ataxia of the arms or legs; no paralysis or wasting; no defect in touch, temperature, or posture-sense. Hearing: right, $\frac{5}{60}$; left, $\frac{1}{6}\frac{2}{3}$. There is otitis media of both sides. Bone-conduction is good. Taste and smell are normal. Laryngoscopic examination is unsat-

isfactory, the pharyngeal reflex being excessive. Heart and lungs are normal.

On February 3, 1891, vision in the right eye has fallen to $\frac{5}{10}$, and the field is further narrowed in the upper part.

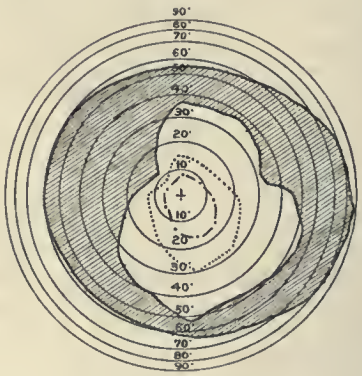
June 3, vision—right, $\frac{1}{50}$; left, $\frac{5}{10}$. The patient has a band-like feeling about the head. The knee-jerks are present.

FIG. 1.



Left eye. Visual field.

FIG. 2.



Right eye. Visual field.

The striking feature about each of these cases is the presence of decided atrophy of the optic nerve with the absence of ataxia, and even of Romberg's symptom. The spinal symptoms were so unobtrusive that both patients sought relief only for failing sight, and in one case the knee-jerks still remain, though diminished and unequal. That optic atrophy prevents the occurrence of other symptoms seems at first sight most improbable, yet there is evidence that in some way it does so. It has long been known that optic atrophy may for years precede other symptoms of tabes. Charcot[1] describes a case of blindness due to primary atrophy, with lightning-pains occurring three years later, followed shortly by gastric crises, but with no difficulty in locomotion as late as twenty-nine years after the onset. In another of his cases blindness, due to atrophy, came on simultaneously with lightning-pains, gastric crises following, but there was no incoördination fifteen years later. He says other such cases might be cited, and reaffirms, as amply supported by increased experience, a former statement that the great majority of all the patients coming into the Salpêtrière with amaurosis afterward develop the symptoms of tabes, though perhaps not until ten or fifteen years later. Had the knee-jerk then been known, its loss would doubtless have led to a somewhat earlier diagnosis. Gowers[1] says: "So marked, indeed, is the contrast between the course of different symptoms that it suggests a certain alternative tendency. If optic-nerve atrophy develops, the spinal symptoms in most cases remain stationary. So, too, of visceral crises. I have known gastric crises to cease when the incoördination began to develop." Walton,[2] of Boston, has collected and reported evidence supporting this statement. After quoting Charcot and citing cases of Gowers and Buzzard, in which optic atrophy, pains, and loss of knee-jerk were the only symptoms for fifteen, sixteen, and twenty years, respectively, he gives an analysis of 66 cases of tabes. Of these, 14 presented optic atrophy, and 6 others, not examined with the ophthalmoscope, loss of sight. Of the 14 with atrophy, 3 exhibited no ataxia, 5 were slightly ataxic, 3 were decidedly ataxic, and, in 3 others, the symptom is not mentioned. The duration of the 8 non-ataxic or slightly ataxic cases was 2, 3, 4, 7, 8, 10, 12, and 12 years, respectively. The general result of this investigation is that in the presence of atrophy of the optic nerves there is a remarkable abeyance of other symptoms, especially of ataxia.

To obtain further evidence as to the practical importance of this apparent antagonism between symptoms, I have studied a series of 40 cases of tabes dorsalis, reported by Marina,[3] of Trieste. These are especially suitable, because, while this particular question is not touched upon (aural and laryngeal symptoms being the special object of research), the patients were generally thoroughly examined. Of these cases ataxia was present in 22, absent in 18. The separation of ataxia and optic-nerve atrophy is shown in the following table:

	Ataxia present.	Ataxia absent.
Advanced optic atrophy (recognized by ophthalmoscope, fields limited, vision one-third or less)	2	9
Beginning atrophy	6	5
Discs normal	3	3
No failure of vision noted; no ophthalmoscopic examination	11	1
	22	18

[1] Leçons sur les Maladies du Système Nerveux, t. ii, pp. 40–46.

[1] Diseases of the Nervous System, Am. ed., p. 102.

[2] "Latency of Ataxic Symptoms in Cases of Optic Atrophy," Boston Med. and Surg. Journ., Aug. 1, 1889.

[3] Archiv für Psychiatrie, Band xxi, Heft 1.

The preponderance of advanced atrophy in the non-ataxic cases is evidently too great to be accidental. Nor is it accidental that of 12 cases in which the ophthalmoscope was not used, 11 were ataxic. The pupils were tested in all of these, and muscular insufficiencies noted in some, so that any failure of sight would also have been noted. It is fair, then, to assume that this group does not include cases of advanced atrophy, and it probably does include most of those with normal optic nerves. One of the two ataxic cases with advanced atrophy was remarkable for a very wide range of symptoms and rapid course; paraparesis and muscular atrophy, as well as ataxia, appearing early. The other was of seven years' duration, and had run the usual course. Up to the last examination the duration of the 9 non-ataxic cases with optic atrophy was 1, 1, 2, 3½, 5, 5, 6, and 10 years (in one not stated), respectively, averaging over 4 years, which is longer than the average time after onset in which ataxia was found on examination in the ataxic cases, although it had doubtless been present at a considerably earlier date in many of them. But, aside from the question of duration, it is evident that if, in a sufficiently large number of cases, there is a greater proportion with optic atrophy in the pre-ataxic stage, then the atrophy must in some way be associated with the prevention of ataxia; for atrophy never disappears, and if these cases went on into the ataxic stage at the usual time it would still be found in the same proportion.

It would be important to know whether degeneration of the auditory nerve in tabes is also more frequent in non-ataxic cases. This is difficult to ascertain because disease of the inner ear is not always easy to diagnosticate, and does not necessarily mean degeneration of the nerve, unless the auditory field is progressively limited.

The ears were examined with unusual care in all of Marina's cases. Disease of the inner ear was diagnosticated in 13 and suspected in 2 of the 18 non-ataxic cases (72 or 83 per cent.); of the 22 ataxic cases it was diagnosticated in 9 and suspected in 4 (41 or 59 per cent.). It, therefore, appears as if disease of the inner ear to some extent excluded ataxia. On the other hand, laryngeal palsies were found twice as often in the ataxic cases as in the non-ataxic.

Romberg's symptom was entirely absent from 7 of Marina's cases. Of these, all had inner-ear disease except one, in which it was doubtful; 4 had advanced optic atrophy; 1 beginning atrophy; 2 normal discs. Contrast this with 29 cases in which, with Romberg's symptom fully developed, there were 14 with inner-ear disease and 5 with advanced atrophy.

The knee-jerk was absent or unequally diminished in the entire series. Of 7 cases with some remnant of it, advanced optic atrophy was present in 2; beginning atrophy in 3; disease of the inner ear in 4, suspected in 2 more; either advanced atrophy or inner-ear disease was present in all except one, and in that one inner-ear disease was suspected.

Walton[1] found the knee-jerk present to some extent in 4 of 9 cases of tabes with optic atrophy; and it was normal in another with loss of sight, but no ophthalmoscopic examination was made. In one of Gowers's[2] cases "all the symptoms of tabes passed away, the knee-jerk returned, optic nerve atrophy ceased to advance, but the patient became insane." It is probable, therefore, that even the loss of knee-jerk may be at least delayed by activity of the disease in the optic or auditory nerve or cerebral cortex. The proof is not likely to be proportionate to the fact, because the presence of the knee-jerk is commonly regarded as excluding tabes.

Dr. L. C. Gray[3] has reported a case of tabes complicated by general paresis, in which the occurrence of mental hebetude seemed to cause an improvement in the tabetic symptoms.

If it be true that there is any mutual exclusiveness in the symptoms of tabes, it not only suggests interesting pathologic reflections, but necessitates some modification in the existing rules of diagnosis. Thus the presence of optic atrophy makes a comparatively small amount of additional evidence sufficient to establish the diagnosis of tabes. Indeed, primary bilateral atrophy alone makes the existence of tabes probable. Nettleship[4] found that of 76 cases of primary bilateral atrophy 58 certainly, and 10 more probably (76 or 90 per cent.), were due to the same causes that give rise to degenerative changes in the spinal cord and brain. Uhthoff[5] found that of 83 cases of atrophy, not neuritic or due to causes in the orbit, 69 (83 per cent.) were due to spinal or cerebral disease. Peltesohn[6] found that of 98 cases of spinal or cerebro-spinal atrophy occurring in Hirschberg's clinic, 78 (80 per cent.) were cases of tabes dorsalis. Combining these statistics it appears that in a case of bilateral atrophy without assignable cause the chances are two to one that it is a symptom of tabes. If the knee-jerk is gone, the diagnosis is practically certain. But the presence of the knee-jerk in such a case by no means excludes tabes. True, Gowers[7] says that if it is present the diagnosis can be justified only by

[2] Diseases of the Nervous System, Am. ed., p. 302.
[3] New York Neurological Society, October 1, 1889 reported in THE MEDICAL NEWS, November, 2, 1889.
[4] Quoted by George A. Berry, "Diseases of the Eye," Am. ed., p. 315.
[5] Ibid. [6] Archives of Ophthalmology, xvi.
[7] Loc. cit., p. 316.

distinct and characteristic incoördination. But this statement is certainly ultra-conservative. No one doubts that the knee-jerk does remain for a time after the onset of true tabes. Indeed, it is probably exaggerated at first.[1] The only question is whether the disease can be recognized in the absence of ataxia, with the knee-jerk present. I think it can, if there is a characteristic combination of minor symptoms, and especially if the negative evidence is neutralized by the presence of such a condition as optic atrophy, which has been shown to exclude the cardinal symptoms to a certain extent.

In the second case that I have just reported, we have the presence of the knee-jerks and complete absence of Romberg's symptom, ataxia, and anesthesia; but against this is to be placed optic atrophy, the Argyll-Robertson pupil, transient ptosis, paresis of the bladder, occasional incontinence of urine and impotence, so that I think the diagnosis is fully justified, even without taking into account the unequal diminution of the knee-jerks.

But little need be said as to the prognosis in this variety of tabes. As to the spinal symptoms, it is certainly comparatively good. Gowers[2] says that most cases do not go beyond the first stage. Unfortunately the atrophy usually progresses to nearly complete blindness, and it would be no consolation to the unfortunate patient to tell him that he will probably be saved from the tortures of a spinal disease, as yet unknown to him, at the expense of sight, the loss of which he dreads above all things. Still, the earlier the diagnosis the less gloomy is the outlook, for unhygienic conditions may be altered and judicious treatment may aid in arresting the morbid process.

P. S.—In the interval between writing this article and reading the proof, I have seen two cases of optic atrophy due to tabes, and a third probably of the same nature. I herewith briefly mention them.

A. S., a male, fifty-eight years old, had a severe fall twenty years ago. Lightning pains appeared soon afterward. He had to abandon his trade, six years ago, on account of failing vision. There is atrophy of both discs; the visual fields are contracted; vision is $\frac{5}{20}$ in each eye; Argyll-Robertson pupil is present; micturition is retarded. The knee-jerks are absent. There is *no ataxia* and *no Romberg's symptom.*

A. G., a male, forty-five years old, noticed that his sight began to fail twenty-five years ago. He has had shooting pains for at least fifteen years past. Vision: on the right there is light-perception; on the left he counts fingers at one foot. The pupils are unequal; Argyll-Robertson reaction is present. The knee-jerks are absent. Romberg's symptom is present. There is very slight, though distinct, ataxia of the arms and legs. The patient had been twice examined by pension-examiners, but complained of nothing but loss of sight. He was much surprised when told that he had a grave form of nervous disease.

G. E., a male, forty-eight years old, had noticed that vision began to fail two years ago. Vision: on the right he cannot count fingers, but he sees the hand; on left, $\frac{5}{60}$. The optic discs are atrophied. The pupils are contracted; they react slightly to light, but well in accommodation. The knee-jerks are sluggish. There are no shooting pains; no Romberg's symptom; no ataxia. The man feels perfectly well, except for his loss of sight.

SHOULD TUBERCULIN BE ADMINISTERED IN PRIVATE PRACTICE?

BY KARL VON RUCK, B.S., M.D.,
OF ASHEVILLE, N. C.

I AM frequently in receipt of inquiries from physicians who contemplate using tuberculin, as to my method of administration, and I note from such inquiries, and also from various publications in the medical journals, that even now an amount of experimentation with this agent is carried out which, in my opinion, is in no wise justifiable, for, if anything is apparent in the voluminous literature upon the subject, as to its practical application, it is that, apart from the favorable results observed, it may become a source of serious injury, if improperly given, or if its effects are not thoroughly understood.

The remedy may also fail to accomplish good results, and disaster may follow its use, when the general management and supervision of the case are in any way faulty; and under the most favorable conditions of dosage, selection of cases, and perfect management, other means are frequently essential in order to effect a recovery, the remedy constituting an aid more or less important, but not an unfailing specific, to the administration of which a cure must necessarily follow.

I believe that my experience of more than a year justifies me now in repeating the statement that the remedy *can be given* with the avoidance of every danger, unpleasant symptom, or discomfort, in suitable cases, under proper management and supervision, and I believe that its influence is then beneficial, not alone because *my* results have been highly satisfactory, but also because trustworthy and able observers have recorded excellent results in cases in which the additional aid of climate and other treatment were not possible factors, as has been the case with my own patients.

Although there are now cases recorded amounting to thousands, in which apparent recovery, or unusual improvement, is claimed to have resulted from the use of the remedy by authorities whom we cannot doubt, and from the records and descriptions

of the cases, the remedy stands in reasonable relation to the cure or improvement. Now, although the curative effects have had frequent corroboration by ocular demonstration of healed tuberculous processes in almost every organ of the body, it must be conceded that if such an effect were demonstrated to be undoubtedly the result of tuberculin employed in only one single case that was truly cured or improved by the remedy, then, under the same conditions, a cure or improvement may again result; and failure to accomplish it must be sought either in the selection of cases, the method of application, faulty management, or conduct of patients while being treated, in the response of the particular organism to the remedy, or finally, in the variations and possible deterioration of the tuberculin itself, but certainly not in its value as a curative agent.

The object of this paper is the consideration of the feasibility of employing tuberculin in private practice, and thus enlarging its usefulness; and by considering the conditions stated, upon which I claim that success or failure must depend, the reader can answer for himself whether or not he shall employ tuberculin at all, or make use of it in hospital or private practice.

1. *The proper selection of cases.* The patient must be in fair physical condition. A loss of more than 20 per cent. of his average weight in health, especially if he is still losing, should for the time exclude him from the treatment until the cause for the progressive emaciation is found and removed.

He must be practically free from fever. As long as he reaches an evening maximum of 101° F., or more, the greatest circumspection would certainly be necessary.

There should be a fairly good heart-action. A pulse-rate (during rest) averaging 112 or more for the time contra-indicates the use of the remedy, as does also the existence of a considerable degree of anemia.

It goes without saying, that the earlier the stage of the disease, the smaller the area of lung involved, the better are the prospects. Regardless of the particular advance of the disease in the particular lung-portion, the vital capacity is the best criterion; if this should have fallen below one-third of the amount which, according to my published table,[1] corresponds to the patient's height and sex, the case should for the time be excluded, until other means shall have accomplished an improvement in this respect.

The presence of considerable fibro-plastic pleural exudations of tuberculous origin requires the greatest caution; cases with infiltration, already giving evidence of beginning breaking down, accompanied by chills and fever, must certainly be excluded.

The presence of a cavity is of itself no contra-indication, but acute inflammatory processes in or about the cavity exclude the case until these are arrested by other means.

Amyloid degeneration in the kidney, liver, and intestine exclude the case.

Tuberculous processes of other organs do not constitute contra-indications in themselves, except when located in the joints and such localities where no outward discharge is possible, unless in the earliest periods of their development; in all other stages, surgical means must precede the employment of tuberculin. Only in the milder cases of intestinal tuberculosis can tuberculin be employed with a prospect of success, and the doses must be very small, beginning with one-twentieth of a milligram.

The most favorable cases are, therefore, those without fever, or with a maximum of not more than 100° F., therefore without acute processes, in still a fair condition of general nutrition, and a vital capacity of two-thirds or more of the amount corresponding to sex and height, a relatively good heart-action and good digestive organs; under other conditions other means must precede, and frequently have succeeded in my hands in preparing the case, so that the treatment with tuberculin can subsequently be employed with benefit.

2. *The proper mode of administration.* There must precede a period of at least a week or more for study, investigation, and observation of the case. No statement of the patient as to his previous condition must be accepted in lieu of such study. The temperature and pulse must be observed and recorded every two hours, the sputum and urine must be examined. At least two comparative physical examinations should be on record before beginning the treatment.

The first, or trial dose, should never exceed one-fifth of a milligram. One-tenth is better in cases in which caution is advised in their selection.

The increase is then by one-tenths up to one milligram, then by halves to five milligrams, finally by milligrams up to ten.

After an injection the patient must be kept free from mental excitement and physical exertion, and all influences must be eliminated that may influence pulse, temperature, or the local tuberculous process.

Records of physical examinations, pulse, fever, respiration, appetite, urine, weight, etc., must go hand-in-hand with the continuance of the treatment.

No dose is ever to be increased until no local response has been manifest to the two preceding doses. General symptoms, especially chill or fever, must never be produced.

The remedy is thus given daily, or every other

[1] Gaillard's Medical Journal, October, 1891.

day, according to the effect produced in the local tuberculous process. All general effects, even when transient, and all local effects lasting more than twenty-four hours, are to be considered as due to an overdose, and require an intermission until they have been absent at least twenty-four hours, and then the dose is to be diminished to the dose that last given had produced no effect upon two successive administrations.

It may be found that the patient now responds to this last dose also, after a local, stimulating, or irritative effect upon the tuberculous process has once been set up, and in such case the preceding dose which had no effect must be adopted. I have thus lately seen a response to seven, then to six, to five, and last to four, but none to three milligrams, but no response again until ten milligrams were gradually reached. At no time was there fever, but the effect appeared in the local tuberculous process, with increased cough, and was manifest by a temporary increase in the physical phenomena elicited by comparison with the previous examination on record, made after the effect of the last active dose had subsided.

In most cases treated by me lately ten milligrams were not exceeded. Frequently I stop at five milligrams, allow an intermission of several weeks, and then repeat the treatment, under a more rapid increase until the previous maximum dose is again reached.

The evidences of successful treatment appear in the course of from two to six weeks, and consist in the subsidence of local auscultatory phenomena, such as râles and crepitation; the harsh, rude, or bronchial respiration becomes less marked, a suppressed, slightly vesicular murmur gradually taking its place; the percussion-phenomena indicate increasing fibroid or connective-tissue changes; cavities become clear, free of râles, and shrink; the patient increases in weight and strength; cough and expectoration become less, and he is sensible of a change for the better.

The occurrence of increasing anemia indicates the combination of oxygen-inhalations with the internal use of preparations of iron, and a reduction in the dose of tuberculin until the blood-making processes improve.

When all moist and dry auscultatory phenomena have disappeared, and fibroid changes are clearly manifest, it is best to stop the administration of the remedy and keep the case under careful observation.

Such administration means almost constant professional attention, daily physical examination; and in cases showing even a slight local reaction, the examinations are even more frequent—two or three times the same day. While no harm may result in a particular case, anything less means to invite relapses and injurious consequences as a result of the treatment by which we hope to, and can obtain benefit. Unless so managed, a slight reaction may escape us, leading with increasing doses to constitutional symptoms, at a time when the indication really is for intermission and subsequent decrease in dosage, and disaster may then be the consequence, the blame falling to the remedy, instead of where it properly belongs. Similar results follow the exhibition of other remedies, when their effects are not carefully observed.

It may be urged that good results have been observed from the use of tuberculin with much less care and caution than I recommend, and this I concede freely. Indeed, such results have followed when the conditions that I strive to avoid by the greatest care and circumspection have purposely been induced. That was, however, the particular patient's "good luck," while in many other cases injury and indifferent results were the consequence of the early experimental and reckless use of the remedy.

In over 4000 injections given by me upon the plan I advocate, I have never seen an injury or even discomfort in a single case, which fact alone would justify all the care and precautions adopted; and with the exception of two or three cases in my early experience, which, as I now understand the selection of cases, were unsuitable for the treatment, improvement, and in many cases permanent arrest and apparent cures have been accomplished, and are still being accomplished, and in the apparently cured cases no relapses have as yet occurred. In no single instance have I failed to bring about improvement.

3. *Faulty management.* In my papers on the "Management of Pulmonary Tuberculosis,"[1] and the "Cure of Pulmonary Tuberculosis upon the Principle of Nutrition,"[2] I defined what constitues the proper management of a patient suffering from pulmonary tuberculosis. Such management is prerequisite, no matter what special treatment is carried out in addition. If we use tuberculin we should, if anything, increase our general precautions to avoid conditions that favor relapses, because with it as well as with any other method, success depends upon maintaining and increasing the patient's nutritive processes, because apart from other dangers likely to follow, any general or prolonged local reaction reduces the patient in weight and strength, and otherwise interferes with his nutrition. To any physician who has closely observed not only the disease, but also the subject of the disease—*the patient*—my statement suffices that consumptive patients are constantly committing errors of various sorts, which are more or

[1] Therapeutic Gazette, August 15, 1889.
[2] Dietetic Gazette, November and December, 1891.

less opposed to the principles that I claim are the bases for success, and neither tuberculin nor any other remedy can protect them from the ill, and sometimes serious or even fatal effects of their errors and indiscretions. On the contrary, the dangers may be increased by the use of tuberculin, at least with some patients, when it shows a decided effect upon the heart-action.

To prevent these, in office or general practice, the patient must be either one of such extraordinary intelligence and unswerving determination as we seldom or never see, or else his case must be an unusually favorable one by reason of an excellent constitution and exceptional recuperative powers. Such patients, however, are not often the subjects of pulmonary tuberculosis.

I find in actual experience, based upon many hundreds of patients, that advice and restraint in one direction or other, and appeals to their determination and steadfast purposes for recovery, are, to a varying degree, required with all patients, and that even then slips occur that throw obstacles in the path of recovery. Conditions calculated to prevent injuries, in the way of personal surroundings and matters of hygiene, comfort, diet, clothing, etc., are seldom secured or enough appreciated by patients in their own homes, or at the boarding-houses and hotels of climatic resorts; neither can the attending physician be constantly present to show and direct the way.

Such being the case under any circumstances the question now arises, Shall we administer so subtle a remedy as tuberculin appears to be to patients in our offices, or upon visits at their residences, and then trust to good luck that the remedy will act favorably?

I doubt that any physician will answer in the affirmative, who, apart from the use of tuberculin, can appreciate the manifold causes that may aggravate the physical phenomena and symptoms in the course of the affection; and if the remedy is to be given only under the precautions I have found essential, how can there be an intelligent procedure as to the necessary repetition and increase of doses?

The fact that, in a given case, not disaster but good results have followed careless administration is no argument whatever in its favor.

I have known of a capital operation performed upon a filthy patient, in a dirty room, by a surgeon who was wanting not only in his own personal cleanliness, but who was utterly ignorant of every principle of antisepsis, and of the modern principles of the treatment of wounds, who during part of the operation had his instruments upon the floor of the room, or upon the unclean bed and table, who applied dirty bandages over and over again, and yet this patient made a good recovery. But who would willingly and knowingly entrust his case to such care, and where is the surgeon that can countenance such work?

In pulmonary tuberculosis, and in other diseases as well, the chances of improvement and recovery become less in proportion as we relinquish advantages that can aid in the attainment of these ends; and so long as an institution can show greatly better results than are obtained in private practice, just so long must the treatment there have the preference, the importance of its adoption depending upon the difference in the results. If, then, tuberculin can be administered more intelligently and more successfully in institutions and hospitals than in private practice, its use should be confined to them, at least until it can be shown that ill effects do not attend its use in private practice.

When good results, and *no ill effects*, from the remedy appear in private practice, then it may become a matter of expediency, but the choice must ever fall to the institution until the results are as good without the safeguards that there surround the patient.

However, every institution is not necessarily a good one, and differences in results may be expected according to individual management, and the painstaking scientific methods of professional administration.

4. *Other aids to recovery.* Apart from a correct and individual management, there are many other aids to the successful treatment of pulmonary tuberculosis that are as important, and under certain conditions more important, than the use of tuberculin, or that of other remedies employed for their effect upon the local condition of the lung.

These include the proper use of climate, a rational treatment of the fever by rest, hydropathic methods and stimulants, singly or combined, to the almost entire avoidance of drug-antipyretics.

It is utterly impossible to successfully carry out such procedures, except in an institution. The treatment of gastric and intestinal catarrh, in addition to a proper diet, frequently requires washing out and direct medication of the stomach, chemical analysis of its contents, etc.—things very difficult to do when the patient needs to be visited at his home.

The pneumatic cabinet in my hands accomplishes good results, and in some cases is an aid I would be entirely unwilling to dispense with. I employ it with evident and well-marked benefit in most cases that receive tuberculin, when no special contra-indication exists.

Because the patient takes tuberculin, or any other remedy, local treatment of affections of the nose and throat, and catarrhal states of the bronchi, are not to be neglected any more than the sys-

tematic out-of-door life in a favorable climate, and the results must in proportion be better as we intelligently combine the various means at our disposal, rather than depend upon this or the other single effort.

I am sure the intelligent reader who gives these matters thought and reflection will readily see that from my position we have in tuberculin only an additional aid in our battle with tuberculosis; one, however, that needs the greatest care and circumspection in its proper use, and that, if administered without the necessary safeguards, may become a greater source of evil than of good.

It is, perhaps, unfortunate that I am the director of an institution for tuberculous patients, because my motives in urging treatment of such with or without tuberculin in such establishments whenever possible, could be easily misunderstood; but without such connection my experience could never have been possible, and I could not have been able to learn and appreciate many things that would have passed unobserved but for the close and constant relation with a large number of such patients.

Dr. Trudeau, of Saranac Lake, and others who have under their charge *charitable* institutions in which the number of patients is of no personal advantage to the director, have all arrived at the same conclusions, being as much in favor of the treatment in institutions as I; and interested members of the profession, who now advise tuberculous patients to pursue other courses, can learn the advantages even without establishing institutions of their own, by comparison of the results obtained.

In this connection I may say that I have never been willing to administer tuberculin to patients living outside of my institution, for the reasons already stated, although I have had, and still have, many applicants for such treatment, and could easily have given the time for such routine injections, the fees for which would have been a considerable personal gain. Neither have the charges to patients in my institution been increased, from the beginning to the present time, because of the additional administration of this remedy, although the amount of professional labors with such cases have been thereby enormously increased.

With the subsiding prejudice created, after most extravagant expectations, by its failure to accomplish impossible results, and by its frequently observed injurious effects, clearly demonstrated by me[1] and others to have been the result of the inexperience of those who used it in its early history upon hopelessly advanced cases, in over-doses, and without the essential precautions, the remedy is now once more growing in favor, especially in Germany, and other places where its real merits are being established by clinical and experimental results.[1] I have had occasion to observe this with prejudiced patients who were admitted to my institution, conditioning that they should not be given tuberculin before it was even proposed to do so. Indeed, there never has been a single patient who, on observing the marked and rapid improvement in other patients receiving the remedy, and the entire absence of any discomfort from its use, did not, without recommendation on my part, ask for its administration, and repeatedly beg for it, when, in my judgment, its use was contra-indicated or unnecessary.

In view of this revival of confidence, I sincerely hope that I may have contributed my share to its clinical understanding, and that my experience with tuberculin may serve other members of the profession sufficiently, so that no sentiment or other motive will be allowed to interfere in withholding the remedy from unsuitable cases, or in adopting its administration with any less precaution than I have found essential.

[1] Weekly Medical Review, August 22, 1891.

NASO-PHARYNGEAL STENOSIS.[2]

BY WILLIAM C. BRAISLIN, M.D.,
ATTENDING PHYSICIAN, LONG ISLAND COLLEGE HOSPITAL DISPENSARY, ETC., OF BROOKLYN, NEW YORK.

BY pharyngeal stenosis is meant any of the states in which the membrane is thickened, so that it encroaches to any extent on the normal caliber of the pharyngeal space, be the thickening of the membrane caused by chronic engorgement of its vascular supply, hypertrophy of its glandular tissue, or deposits of inflammatory products within its structure proper. There is no practitioner, especially in our seaboard cities or towns, that does not come in almost daily contact with these cases. Their extreme prevalence, however, does not tend to make their average treatment meet with the measure of success that is desirable. The result of this non-success on the part of the general practitioner is to send great numbers of cases into the hands of the specialist.

The specialist must always be dependent on his confrères in the wider field of general practice for a large portion of his work; yet it would seem that referred cases should properly consist of that rather small proportion that requires special technique in operative procedures for its relief; and certainly a great many cases come to the specialist that can be relieved, if not cured, by some simple methods rightly applied.

[1] Southern Medical Record, September, 1891; Deutsche med. Wochenschrift, November 19, 1891; Medical World, December, 1891.

[2] Read at a meeting of the Long Island Medical Society, November 5, 1891.

It may be useless, but it is more accurate, to define the naso-pharyngeal cavity as that space (entirely out of direct vision), the lower boundary of which is on a level with the free border of the soft palate; the upper boundary of which is limited by the basilar portion of the occipital bone and body of the sphenoid bone; the posterior limit of which is the vertebral column and muscles; the lateral boundaries of which are the pharyngeal constrictors and other muscles of the neck. This space opens anteriorly into the posterior nares, and faces the posterior border of the septum and extremities of the turbinated bodies. This space provides a passage for the air on its way to the lungs through the nose. It contains a great quantity of glandular tissue, which moistens to some extent the air so inspired. During the process of deglutition this glandular tissue is excited, its ordinary secretion is increased in amount, and lubricates the mucous membrane of this portion of the alimentary tract with viscid mucus. The naso-pharyngeal cavity thus belongs, in a specialized sense, to the alimentary tract, and, in a general way, is part of the respiratory tract. Its disorders thus become a source of considerable importance in their bearing on both normal respiration and normal digestion. It is thus easy to appreciate how, conversely, conditions of abnormal quality, density, etc., of air impinging upon its walls, and also conditions of gastric derangement, most profoundly affect this cavity.

The practical importance of a narrowing of this very important section of the respiratory tract is at once rendered clear by considering for a moment the mechanism of respiration.

The chest is practically a *cylinder* for the reception of air necessary for oxygenating blood; the diaphragm, a piston; the nasal canal, part of the tube of normal communication with the air outside. If we give such a motion to the piston as shall increase the inter-cylindrical space, the inter-cylindrical pressure will decrease in direct proportion to the rapidity of the motion of the piston, and in direct proportion to the size of the conducting tube. In other words, while the increase of inter-cylindrical space is constant, the smaller the conducting tube the less the atmospheric pressure in the cylinder; and the larger the canal the nearer the inter-cylindrical pressure will approach the outside atmospheric pressure. Consequently, when we have the caliber of the nasal canal narrowed, the motion of the diaphragm produces a condition of the inter-respiratory air, now less than its normal density, then greater than its normal density. In other words, it produces an alternate rarefaction and condensation of the inter-respiratory air.

This damaging influence, affecting first the glandular apparatus of the pharynx, has more effect on the whole surface of the respiratory mucous membrane than I think we are at first inclined to believe. The constant change of pressure produces first a tendency to congestion of the whole of the mucous membrane, and it also acts as an excitant to the glandular secreting apparatus. The former tends to a thickening through subsequent inflammatory deposit; the latter to an hypertrophy of glandular tissue. Thus we get increased secretion of mucus; changes in the voice, as indicated by loss of resonance; tendency to tire easily by thus giving the vocal cords more work to do; consequent hoarseness from resultant congestion of the cords. We also get changes in the hearing (often not noticeable to the patient himself, but demonstrable by the watch-tick or other test), due to partial closure of the pharyngeal opening of the Eustachian tubes by the hypertrophied membrane. A Eustachian catarrh is thus being directly induced by the alternation of lowered and heightened inter-pharyngeal air-pressure.

Aside from the deteriorating effect upon the pharyngeal functions of air of improper density, an improper quality plays an important part. This is forcibly illustrated in the cases of patients who suffer from abnormal secretions of the naso-pharynx while in our seaboard cities, but who are promptly relieved by going to the mountains, although the old symptoms manifest themselves immediately on their return. Hence, conditions of moisture are an aggravating if not a causative factor in these cases. There are doubtless other impalpable and unmeasurable factors in our climate, as, for example, salt spray, marsh gas, dust, etc., which irritate to no small extent the mucous membrane of the respiratory tract.

Treatment largely resolves itself into an appreciation of the causes of the hypertrophies of the naso-pharynx.

As a stricture of the urethra keeps up behind it a chronic inflammation with its relative discharge, so a stenosis of the *nasal passages* acts as a continued source of irritation to the mass of glands in the vault of the pharynx. Each of the many varieties of disorder producing nasal stenosis is, therefore, an exciting or an adjuvant cause for a naso-pharyngitis.

The importance of this fact in the treatment of *all* chronic inflammations of the respiratory tract, it seems to me, cannot be over-estimated. The naso-pharynx, when suffering from a stenosis, either partial, as in chronic congestion, or complete, as in adenoid hypertrophies, presents, with varying proportions, indications for treatment of—first, abnormal secretions; second, improper conveyance of air to, and preparation of air for the lungs.

Conditions of improper conveyance of air, of

improper preparation of air for the lungs, and of abnormal secretion, should be subjected to treatment directed to—first, the abnormal condition of the secreting apparatus; and second, to the stenosis.

Of course, the most common point of narrowing is in the nasal cavity; and while this demands its own treatment, its treatment does not affect the stenotic condition of the pharynx which it has aggravated, or caused. The same is true of any of the other causative factors of pharyngeal stenosis. In fact, it has been a matter of observation by patients that secretions of the pharynx seem to be *increased* after successful treatment of a nasal stenosis. This error is made simply because the mucus secreted by the hypertrophied glandular tissue of the pharynx is more easily dislodged when the column of air inhaled through the nose is of a greater caliber.

In directing any form of treatment to the naso-pharynx it is, perhaps, useless to emphasize the importance of accurate appreciation of both the *degree* and the *situation* of the stenosis.

One form especially distinguishable is that in which the area of greatest stenosis is situated immediately at the posterior, or pharyngeal, opening of the nares. These cases are, of course, associated with hypertrophy of the nasal mucous membrane.

We have one form of stenosis, once called Thornwaldt's disease, which is associated with the abnormal formation of a cyst-like cavity in the midst of the pharyngeal gland, containing pus or mucopus.

The pharyngeal gland (sometimes badly called third tonsil), in its acute as well as in its chronic inflammatory states, is the cause of partial stenosis. The temporary stenosis of acute catarrhal naso-pharyngitis is self-limited. The chronic naso-pharyngitis constantly presents symptoms of a greater or less degree of stenosis.

It is the excessive form of hypertrophy of this glandular tissue, constituting the so-called *adenoid growths*, that is so frequently met with in children.

These different forms of hypertrophy often originate from the diseases of childhood—for example, measles or scarlet fever. They are sometimes congenital. They are commonly concomitants of, or sequelæ to, hypertrophic rhinitis, and present an almost similar condition of the mucous membrane. Hypertrophic rhinitis is usually the result of repeated colds. In these cases the membrane becomes accustomed to a chronic congestion. The normal caliber of the arterioles is increased—at least, the resistance to any increase of arterial pressure is decreased—so that in addition to the deposit of connective tissue we have a condition of the mucous membrane abnormally responsive to a chilling of the body-surface.

Nearly all the *milder* forms of hypertrophy of the pharyngeal membrane result from abnormal conditions of the *nasal* mucous membrane; the air being on this account improperly prepared for respiration, becomes extremely irritating to the pharyngeal membrane, and hence the resulting pharyngitis.

As I have said, in order to proceed intelligently with our treatment, we should have a clear idea of first—the degree of stenosis; and second, the location of the point of greatest encroachment on the caliber of the pharynx. For this acquisition of objective symptoms most of our books on this and kindred topics refer us to our rhinoscopic mirrors. This method is not unattended with difficulty, and this fact alone, I have been more than once convinced, has been the cause of debarring many busy men from anything like a successful *modus operandi* in treating this condition. It is difficult, because the procedure depends so largely on the co-operation of the patient, as almost everyone thus treated requires some training in order to insure success. In most cases the first attempt at posterior rhinoscopy induces an involuntary attack of retching, which is usually sufficient to discourage any further procedure.

This condition of affairs regarding such an important and so commonly affected a portion of the anatomy, I do not consider warranted. We are apt, I think, to forget that we have a method of examination of the pharynx literally at our finger-tips, and one requiring no instrumental assistance whatever. The method I refer to is the simple introduction into the naso-pharynx of the forefinger. There seems to me to be no reason why, when for any reason a direct inspection of the pharynx with the rhinoscopic mirror is impracticable, we should not employ this method in routine practice.

The questions to be decided by our examination are: First, What is the condition of the pharyngeal mucous membrane? and second, Whether there is sufficient room in the pharynx for a proper method of breathing. These points are perfectly ascertainable by this method.

Treatment directed solely to the relief of the stenosis, in the cases depending for their etiology on such stenosis, though absolutely essential, is not sufficient for the removal of the changes once brought about in the glandular structure of the naso-pharynx. We must treat the hypertrophy of the membrane by methods aiming at the relief of such hypertrophy. It will not otherwise tend to a restoration to the normal state. The methods used will, of course, depend upon the degree of tissue-changes, the amount of tissue-thickening, and the position of greatest hypertrophy.

If the membrane is in a condition of constant

hyperemia or of constant congestion, simple applications of mild astringents, in the form of sprays, or of solutions applied with the cotton-holder, will be found effective.

In conditions of severer congestion with considerable thickening, it is necessary to use stronger astringents, in the form of powders, astringent solutions applied with a cotton-holder, or applications of caustics. When the hypertrophy has reached a condition that involves a considerable stenosis, with obstruction to the free passage of air, the removal of some of the superfluous tissue is called for. Here we may use caustics, corrosive acids, or the galvano-cautery, or other instrumental means. When we have the tissue completely filling the cavity, as in the condition called adenoid growths, or when the tissue is soft and easily broken down, it should be removed by instrumental means. Numberless instruments have been devised for this purpose, among the most useful of which I consider the various forms of forceps. These are constructed with a view to tearing away, rather than cutting the tissue. Some authorities consider them on this account rather unsurgical. The tissue is so soft, however, especially when of the adenoid variety, that forceps are well adapted to this purpose. There is less bleeding, too, than when a sharp-bladed instrument is used. The various curettes, manipulated either through the nose or the mouth, are exceedingly useful. When the hypertrophies exist around, or just within, the orifice of the posterior nares, the snare is especially useful.

No better instrument has been devised, I believe, for these soft masses than the fore-finger of the right hand, when the nail is sufficiently strong and sharp. It is especially useful in the cases of children, in which time is such an important factor. While using it no illumination is necessary, as the finger conveys to the operator all desirable information through the sense of touch.

In the cases in which it is desirable to use a caustic, either as a curative measure itself or following an instrumental removal of tissue, I have found acids to answer a useful purpose, especially chromic, nitric, and acetic acids. They are corrosive, however, and must be handled with care. It was with the view of eliminating the possibility of applying them to any other than the desired spot, that I had made a glass *porte-acid*. It is simply a glass tube, about ten inches in length, bent at about an inch and a quarter from its distal extremity, at about a right angle to the direction of its original axis, with a rather short curve. It is flanged at its distal extremity for the last quarter of an inch. Through its canal is passed a wire, the protruding proximal extremity of which is manipulated by the disengaged hand. The distal extremity of the wire is armed with the corrosive substance, and withdrawn into the flanged extremity of the tube. It is now entirely protected from contact with the tissues, and the instrument can be inserted into the fauces, and carried to the point in the pharynx which it is desired to cauterize. When this is done, one hand holds the instrument in position, and the other hand pushes the wire armed with the caustic against the tissue for the desirable length of time; or, if desired, sweeps over its surface. The wire is again withdrawn, and the instrument removed.

In using nitric or lactic acid, a pledget of cotton, saturated with the pure acid, is used. In using chromic or acetic acid, a few crystals are fused on the end of the wire.

The instrument can be made with an alcohol lamp and a glass tube.

It is of the utmost importance to discover and to remove the *cause* of pharyngeal stenosis in each individual case. This is especially to be emphasized when the cause is *nasal stenosis*, whether this obstruction consists of mucous membrane, bone, or cartilage. These cases, when successfully treated, give us some of the most satisfactory results in this department of surgery.

ANGINA PECTORIS.[1]

BY HERBERT D. BIXBY, M.D.,
OF GRANDVIEW, ILL.

THE sufferer from angina pectoris is without warning attacked by a sense of oppression in the precordial region, which is rapidly followed by a well-defined, severe pain, radiating over the left chest, sometimes to the right as well, and from the chest to the left shoulder, whence it extends into the arm and rarely into the forearm, and accompanied by a sense of suffocation. The pain may also shoot up the neck. The arm seems to be of enormous weight, and there is severe pain upon movement. No position in which it may be placed gives relief, while there is a disposition to relax the affected side by an inclination of the body. The face is pale, the features expressive of intense anguish. Respiration is restrained, for movement of the chest wall intensifies the agony; and the heart is either slowed or beats irregularly. The patient attempts to assume a position that will relax the muscles of the thorax and arm, and may either take a sitting or standing posture, being careful, however, to secure support.

Patients are not talkative during a paroxysm, every inspiration required in the act of conversation

[1] Read at the forty-fourth annual meeting of the Æsculapius Society of the Wabash Valley, held at Paris, Ill., October, 1890. Dr. Bixby was for many years a victim of organic heart-disease and a sufferer from frequent attacks of angina pectoris. He died October 31, 1891.

being accompanied by an acute pang. All movements or jars increase suffering and there is often a strange sensation as of approaching death.

These symptoms, though passing rapidly, sometimes not lasting more than a few moments, may be likened to the slow and easy motion of a train of cars as it leaves a station, but at each second adding to its momentum and intensity, until it is rushing along at reckless speed, pounding, racking, and tearing along, until the patient dreads the next move and fears instant destruction—then, by the same imperceptible change there is a gliding, easy slackening of signs and soon the countenance itself clears a little, and with a sigh of relief he feels well. Such is the course of symptoms in a well-developed paroxysm. The symptoms may vary; the arm may not suffer; the paroxysm may be so mild as as to be almost disregarded.

What is it? For years that question has been asked, and as yet it is practically unanswered. The diversity of opinion as to the nature of the affection is illustrated by the number of names that have been given it, twenty-four in all, based upon phenomena that seemed to be characteristic. The common name, angina pectoris, is as unmeaning as any.

From a clinical standpoint there seems but little if any advantage in considering the affection under the two forms, true angina pectoris (in which there is disease of the heart) and false angina (in which there is no recognized heart-lesion). I might say that no clinical distinction can be determined; and the pathology of the disorder is at best uncertain. It is true that in some cases in which death has occurred, in one, ossified or obliterated coronary arteries have been found; in another, fatty degeneration of the heart; and in another, some other morbid condition; but similar lesions are found in cases in which there had never been attacks of angina. The affection has been considered as a neuralgia, but pure and simple neuralgia it cannot be; for while neuralgia is strictly a nerve-pain (and pain enough there is in angina), the pain is so different from the indescribable, agonizing sensations of angina pectoris that the latter must be looked upon as a neurosis; and here we have a clear, decided statement that we are lost. So we accept the neuroses as the category into which angina pectoris falls, and qualify it further by the prefix vasomotor. Some writers prefer to call the disorder angina pectoris when there is recognized organic heart-disease, but under all other circumstances to call it simply a neurosis. This seems like a distinction without a difference, for with or without heart-trouble the affection is a neurosis, the heart-trouble having no clinical significance.

The pallid skin, indicative of disturbed circulation, the slowed or irregular heart's action, accompanied by pain in the thoracic respiratory muscles, seem to point more surely to a centrally impeded or deranged innervation affecting the capillaries than to organic heart-disease. With this conception we can understand why the symptomatic phenomena may be irregularly produced, one part affected and another not, accordingly as a greater or smaller number of vasomotor nerve-centers is disturbed. We also find that angina pectoris may result from organic or functional irritation of the terminal filaments of the pneumogastric nerve supplying the heart, lungs, liver, stomach, or intestines, the sense-impressions being conveyed to its nucleus in the medulla and communicated to the vasomotor nuclei. The vasomotor centers being distributed throughout the cord, as well as in the medulla, are irritated, whether from nutritive defect or otherwise, the direct cause being conjectural; the capillaries of those parts or organs from which the disturbance emanates are contracted; the blood-pressure is increased and the circulation is diminished, as indicated by the visible signs. The disturbance of circulation cries for relief, and the excruciating pain becomes a landmark for the location of the organs involved, and furnishes indications for treatment during the paroxysm, as well as in the intervals between paroxysms.

The means at hand for treating the spasm can now be plainly indicated: Ether, chloroform, morphine hypodermatically, and amyl nitrite. Of these, morphine and the nitrite are preëminently the best. Of the latter, from two to five drops may be given by inhalation. Amyl nitrite is rapid in action, stimulating the vaso-dilator centers and causing a flush to appear. With the reëstablishment of the capillary equilibrium, the symptoms of the paroxysm subside. It must, however, be remembered, that the nitrite affects the entire vaso-dilator system (especially that controlling the head), and by increasing the circulation in other parts, arm and extremities, sometimes causes a disagreeable sensation of fulness. It is therefore a remedy that must be used with circumspection. If confided to the patient, only a few doses should be prescribed and these with written cautions.

Many of the attacks are so short that the paroxysm may pass before medicinal treatment can be employed. As the spasms are, sooner or later, likely to recur, the case should be under persistent and prolonged treatment during the interval. Should the attack be concurrent with cardiac lesions these should receive due attention and be treated as they would under other conditions; nevertheless a general course of nerve-tonics and such other judicious medication as may be called for will prove satisfactory both to patient and practitioner. It is especially in the form designated false angina that we

may hope for some permanent good from treatment. This condition is mostly found in those of neurotic tendencies, of rapid growth, poorly nourished, or suffering from gastralgia, enteralgia, indigestion, hyperemia and torpidity of the liver. Let us not ignore these cases, but remember that the nerve is simply the means by which the existence of peripheral disorder is communicated to the central organ —the brain.

For the treatment during the interval, arsenic holds a position to the general condition similar to that of amyl nitrite during the paroxysm. For all neuroses, in fact whenever a nerve-tonic is called for, arsenic is a remarkable remedy; but as in the case of the nitrite, it must be used discriminatingly. In some unknown way, arsenic greatly assists the nutritive processes. According to circumstances, iron, nux vomica and the phosphates, given alternately or with arsenic, may be found necessary.

ORIGINAL LECTURE.

AMPUTATION AT THE HIP-JOINT BY WYETH'S METHOD.

A Clinical Lecture delivered at the Jefferson Medical College Hospital, February 3, 1892.

By W. W. KEEN, M.D.,
PROFESSOR OF THE PRINCIPLES OF SURGERY AND OF CLINICAL SURGERY IN JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

Gentlemen: The operation that I have to do before you to-day is a very rare one. The surgical members of the Faculty of this College have performed only five operations of this kind, but these five have been remarkable in one respect. The late Professor Joseph Pancoast did two amputations at the hip-joint; the first one was done at the Pennsylvania Hospital in the earlier part of 1860—just before I began the study of medicine —and in this case, for the first time, he adopted the method of preventing hemorrhage by an abdominal or aortic tourniquet; the case recovered. His second case was done in 1865, in the old College building, and also recovered. The late Professor Samuel D. Gross first operated in 1862, at the Philadelphia Hospital — an operation that I had the pleasure of seeing; his second was performed in 1865, and his third, in this amphitheater, in 1879; all three recovered. You observe, therefore, the remarkable fact that my surgical predecessors have done five amputations at the hip-joint with five recoveries. It must be remembered, also, that these operations were in the pre-antiseptic days, and that the mortality of hip-joint amputation varies from 40 to 93 per cent. It is, I hope, a happy augury for the result in this case. Let me now give you the history of the patient:

Mrs. T., thirty years of age; residence, Bahia, Brazil; entered the Jefferson Hospital January 19, 1892. She was born in Texas, the family history being good. A brother was never very rugged, but has no organic trouble. At nine years of age the patient had her right arm fractured above the elbow, with injury of the musculo-spiral nerve; this produced wrist-drop that has never passed away, and the muscles of the arm are wasted. She had whooping-cough at thirteen, which left her with a bad cough for five or six years. Her greatest weight was 106 pounds, and she now weighs 101 pounds. Her height is five feet two inches. She married at twenty, and immediately went to Brazil as a missionary, since which time she has never been very strong. She has had three living children, and one miscarriage at three months. Two years ago she had a severe attack of smallpox, and, while recovering, an abscess formed at the seat of the old fracture of the arm.
